A New Air Circuit Breaker With 250,000-Kva Interrupting Capacity

Discussion and author's closure of paper 41-32 by R. C. Dickinson and R. H. Nau, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 197-201.

D. C. Prince (General Electric Company, Schenectady, N. Y.): I am repeatedly amazed to find how much of our present art was originally conceived by such grand old masters as Professor Elihu Thomson. The circuit breakers described by Dickinson and Nau and by Boehne appear to have been inspired by a patent granted to Professor Thomson in 1926, the essence of which is shown in figures 1, 2, and 3.

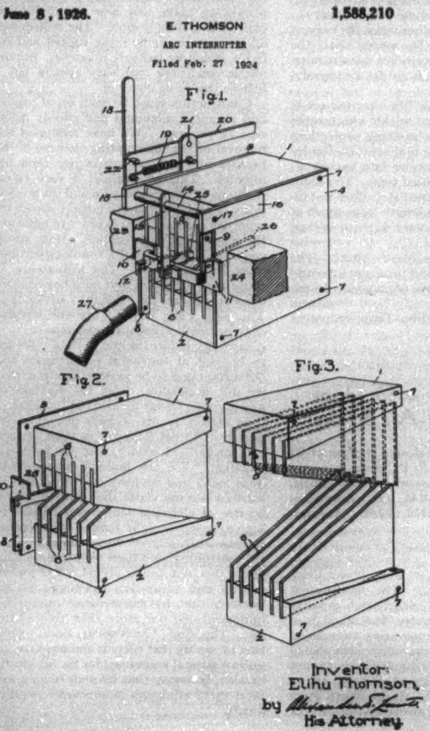
Reading from the patent specification: "Figure 1 shows a combined switch and arc extinguisher. The arc extinguisher is preferably constructed throughout of insulating material and comprises members 1 and 2, which together with plates or slabs 3 and 4 form a passageway open at its two ends. Extending through this passageway in the direction approximately parallel to the sides 3 and 4 is a group of plates 5 supported in any suitable manner by the member 1. A like group of plates 6 partially overlapping or interleaved with but spaced from the plates 5 is supported by the member 2." Later, it is mentioned that these plates may be made of highly compressed asbestos sheets, and still later, "It will be readily understood that an arc between the terminals 10 and 11 will pass the edges of the plates 5 and 6 in a transverse direction, and that if it is forced into the passageway of the extinguisher its length will be greatly increased both due to the fact that it is bowed or bent and because it is forced to follow a zigzag path around the inner edges of the plates. The length of this zigzag path of course increases as the arc is forced farther and farther into the passageway."

These two papers are, therefore, another tribute to the vision of this pioneer.

In examining and comparing the two papers, Mr. Boehne states that in his design the circuit is interrupted by introducing resistance, which improves the power factor, bringing the current more or less into phase with the voltage at final interruption. On the other hand, in the Dickinson-Nau paper, the statement is made that the current is allowed to get to its normal zero in the cycle, whereat intensive deionization is provided to establish dielectric strength. These two statements would appear to be at variance, but the oscillograms produced by the two sets of authors are almost identical, as shown by figure 4, which compares arc drops from figure 7 of the Dickinson-Nau paper with figure 14*a* of the Boehne paper.

In contrast with figure 4, the operation of the circuit breaker described in the paper, "A Conserved-Pressure Air-Blast Circuit Breaker for High-Voltage Service," by Rankin and Bennett, shows an entirely different behavior. Figure 5 is an enlarged portion of figure 8 from that paper, showing the moment of current zero. In this breaker the arc drop is practically negligible so that there is no tendency to bring the current to zero along with the voltage zero as in the case of the Magne-Blast breaker.

Instead of introducing resistance, the operating of this breaker consists of introducing unimpaired dielectric between the contacts at and after the current zero. I am not suggesting that either of these methods of arc interruption is better than the other but indicating that they are very different phenomena, each of which may be the better for some particular application. More directly, the resistance method is quite immune from recovery rate, that is, it operates with equal ease regardless of the recovery rate characteristics of the circuit. On the other hand, it will be noted from the oscillograms that a considerable amount of arc energy is involved. This, however, is of little moment, for the circuit breakers under discussion are relatively small. The air-blast type of circuit breaker is particularly adapted for large interrupting capacity and the fact that it has almost no losses stands it in good stead. For all such applications, the recovery rates are easily predicted so that ample recovery rate capacity can be incorporated in the designs.



Figures 1-3

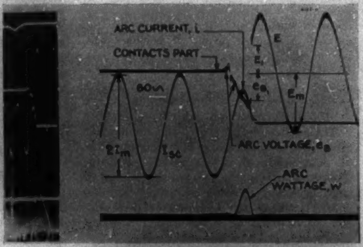


Figure 4 (right)

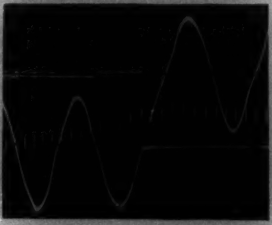

Figure 5 (right)

E. W. Boehne (General Electric Company, Philadelphia, Pa.): The authors have presented an interesting paper. One feature of particular interest is the magnitude of the arc voltage and the corresponding shift in phase angle. The part played by the slight, but costly, staggering of the slots in the chute structure, as shown in figure 2, would be of interest. These phase-angle changes exhibited in the oscillograms, some of which exceeded the angle which produces maximum wattage, give rise to earlier current zeros than would have normally occurred. These facts are not in agreement with the statement appearing on page 197, column 3, namely, "It has been found that definite advantages exist in utilizing a relatively short arc and permitting the current of the arc in interruption to go to its normal zero in cycle. . . ." The authors' conception of "normal current zero in cycle" should be defined. The shift in phase angle, away from the natural cyclic current zero, accompanied by energy increases up to about 45 degrees, has brought about features of the new design expressed by the authors on page 197 in the sentence "The added arc length and distance of arc travel required greater venting to exhaust and deionize the hot gases." This greater venting, in spite of twice the number of insulating plates, is confirmed by the energies available from the oscillograms presented. It is agreed that energies are not the criterion of performance. In fact, the authors have apparently sacrificed energy to achieve the beneficial "low recovery voltage following current zero" as mentioned on page 198, column 2. The answer may lie in the fact that we must first ionize before we can deionize.

A study of figure 11 of the paper "The Geometry of Arc Interruption" shows that rapid reductions of recovery voltage (e_r) do not occur until after the phase-angle changes of more than 45 degrees have been realized. A study of these relations shows the great advantage in having a chute geometry capable of producing phase-angle changes which exceed 90 degrees. As this unity power-factor phase angle is reached both recovery voltage and energy are decreasing at their maximum rates. It becomes apparent that phase-angle changes up to 30 or 40 degrees leading are desirable. Recent random single-phase tests have produced leading phase-angle interruption in excess of 60 degrees with the Magne-Blast breaker.

The authors' reference to the small wear on the arc chamber parts is in confirmation of data collected in thousands of tests. This statement is a measure of the negligible wear experienced when an arc of smaller energy is distributed over a much larger surface, particularly when the surface presents no stopping point for the arc.

R. H. Nau: One might infer from the discussion given by Mr. Boehne and Mr. Prince, of the General Electric Company, that they do not appreciate the advance that has been made in the design and operation of the new magnetic De-ion breaker. To elucidate briefly, the statement, "the period of relative low recovery voltage following current zero" has reference to the transient recovery voltage in its first one-eighth to one-fourth cycle. In practical circuits this time is 2.5 to several thousand microseconds. Obviously the transient recovery voltage is low during this initial period regardless of the location of the point on the 60-cycle voltage wave about which the transient recovery voltage begins to oscillate. The magnetic De-ion breaker will withstand peak recovery voltages which might occur in zero power-factor circuits following interruption.

Mr. Boehne relates at length in his paper, "The Geometry of Arc Interruption," the advantages of low arc energies and high arc voltages, yet in his discussion he says, "It is agreed that energies are not the criterion of performance." The high arc energy of "loop 1" of figure 12*a* in Mr. Boehne's paper shows that continued arcing may be caused by higher energies. Undoubtedly, it is not agreed that breaker performance is independent of the arc energy involved.

Several dominant features set the magnetic De-ion and "Magne-Blast" breakers far apart. The magnetic field as used in the "Magne-Blast" functions primarily to lengthen the arc. Further, this field is produced by a multiplicity of coils, each having many turns. In the magnetic De-ion breaker an intense transverse field, which is produced by one coil advantageously located, is used to produce deionization at current zero and establish high dielectric strength. The high dielectric strength enables the magnetic De-ion interrupter to withstand recovery voltages which may occur following interruption when the current is not suppressed. It seems that the "Magne-Blast" breaker relies upon a near-to-unity power-factor circuit for a successful interruption.

In the "Magne-Blast" breaker the arc is lengthened to many feet within a serpentine path produced by interleaving projections or slabs; while in the magnetic De-ion interrupter the arc is swung into narrow V-shaped slots having closed tops. The slight stagger of these V-shaped slots does not increase the possible arc length by as much as six per cent, and this total length is less than one-fourth that incurred by the serpentine path of the "Magne-Blast" chute. The magnetic De-ion breaker produces interruption by the true principle of magnetic deionization, which has already been described. No inference to the Elihu Thomson patent can be obtained.

A Vertical-Flow Outdoor Compressed-Air Breaker

Discussion and author's closure of paper 41-54 by L. R. Ludwig and B. P. Baker, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 217–22.

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The development of a dependable high-voltage, high-capacity circuit-interrupting device, free of oil is of great interest to all operating companies. Full co-operation and encouragement should be given to research manufacturers toward the practical achievement of such equipment. The engineers of the West Penn Power Company have already witnessed the operation of this breaker and have constructively analyzed and criticized its design and assembly. We believe its advantages have great opportunities for future applications. We have analyzed and made suggestions for location and ratios of protective current transformers and believe that the characteristics of the wound-type current transformers have considerable advantage over the former bushing type available in oil circuit breakers. Their location on one side of the breaker only seems satisfactory. The use of present-day standard capacitor potential devices mounted on an extended steel bracket on the line side of this air-break switch is a suitable substitute for the bushing potential device. For carrier-current relaying application, line traps or carrier choke coils are necessary and we have suggested that they be supported on the top of the coupling capacitor and current transformer provided they are erected on suitable center-lines. We then have a basic device to which is added present-day standard auxiliary equipment which should allow for suitable standardization and aid in reducing costs.

For the control of this new development we deviate from standard and proved electromagnetic facilities such as closing and trip coils, and turn to a pneumatic operational system. The manufacturers know they must and I believe they are doing their utmost to make this new air application entirely free from trouble. The system and all its parts must be quite rugged and reliable, which we feel sure it can be. Atmospheric conditions will vary greatly but I believe this is no obstacle.

Construction must be such as to require and permit a minimum and speedy maintenance program. We have witnessed the removal of the interrupting element of the breaker under discussion in less than ten minutes. This we consider a very essential item. The necessity for and the accessibility of all parts requiring paint should receive due consideration in order to minimize the amount of maintenance. State safety codes for clearance and air-tank inspections must be considered. The availability of single-pole operation and automatic immediate reclosing has definite advantages. The West Penn Power Company has one of these breakers on order and hopes to have it in service before the end of 1941. We are so hopeful of successful performance and the advantages to be gained therefrom that we will, if possible, delay the purchase of any more oil circuit breakers of this class.

In answer to Mr. Edsel's one question, namely—"Is the industry in need of such equipment?"—I wish to cite the following situation. We are building transmission lines today and we have operating data to substantiate our claim that these lines will be free of electrical faults over periods as high as seven or eight years. This reduces the required automatic functioning of breakers controlling such lines to not more than one or two in a similar period. The station control and protective equipment should be such that its maintenance outage requirements be not more than that of the line. Therefore, I answer Mr. Edsel's question by saying that there is and has been for at least several years need for an air circuit breaker, believing that its performance will meet these minimum maintenance requirements.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The writer has discussed features of outdoor compressed air circuit breaker design in connection with the Rankin and Bennett paper and most of these points apply equally to the Ludwig and Baker paper.

The outstanding feature of the Ludwig and Baker paper is the impressive test data taken under severe laboratory restored voltage conditions, which demonstrated the high interrupting capacities obtainable with the particular interrupter design presented by the paper. The provisions for easy inspection of the interrupter are noteworthy and a complete dismantling of the interrupter unit takes only six to eight minutes.

J. R. North (The Commonwealth and Southern Corporation, Jackson, Mich.): These two papers present interesting information concerning designs of outdoor high-voltage air breakers. In this class of service the conventional type of oil breaker has given a very good account of itself and in most installations the matter of oil fire hazard has not been considered to be a major factor in the application and selection of equipment. Consequently it is our rather definite opinion that the need for outdoor air breakers should be strongly evidenced before expensive commercial developments are embarked upon. It would also seem that the relative cost of outdoor air or oilless versus outdoor oil breakers would be an important factor and we would like to inquire of the authors as to the estimated relative cost in the different voltage classes.

H. P. St. Clair (American Gas and Electric Service Corporation, New York, N. Y.): After studying these papers and listening to the presentation, I find it difficult to discuss them separately since the devices described have important features in common. While it might appear that two successful high-voltage compressed air interrupters have been developed along radically different lines, at the same time both use actual flow of compressed air at fairly high pressures and both take advantage of the volatilizing characteristics of fibrous insulating material to produce gas which assists in the interruption of the arc.

The breaker described by Messrs. Ludwig and Baker appears to be an ingenious and effective device which really works judging by the impressive performance figures of tables I and II and the accompanying oscillograms. In that connection I should like to ask one or two questions of the authors:

1. In table I, there are shown a number of interruptions, with currents varying from 3,300 to 8,250 amperes and with arcing time varying from 1.4 to 2.1 cycles. I should like to ask if these results indicate that on these tests the arcing extended to the lower half of the interrupter. If so, is there any explanation why in some cases the arc interrupted in the top half only, and, in others, with no apparent correlation as to the current interrupted and the recovery rates involved, the arc extended to the lower half?

2. In test 18 a high value of current (8,900 amperes) was obtained partly by reason of a large offset or d-c component and this offset was still quite a large percentage at the final interruption. With such a large degree of asymmetry would it not be expected that the reduction or difference between the actual tested recovery rate and the calculated circuit recovery rate would be considerably more than that apparently indicated by the cathode-ray oscillograms taken on these tests? Such a reduction does not seem to have occurred on any of the tests since the ratio between test and circuit values is fairly constant throughout.

3. It would also be of interest to know the over-all time, that is, from trip impulse to interruption, obtained with this breaker.

The interrupter described by Messrs. Rankin and Bennett makes use of what would seem to be a sound principle in taking advantage of the increased dielectric strength of air under pressure. While it is not possible to compare the results as to arcing time between this and the vertical flow interrupter, the over-all time indicates a fast breaker.

Both types of breakers seem to offer advantages in the application of ultrahigh-speed reclosing which is now far beyond the experimental stage and a highly successful tool in system operation. The comparative lightness of moving parts and shorter distance of travel both lend themselves to this purpose.

Speaking in a general way of both of these developments, while it is probably true that many years of research and experience in the design of oil circuit breakers have provided something to start on, nevertheless it is significant that in a relatively short time and in virtually a first attempt two separate groups of engineers have produced results which one might say took a lifetime to obtain with oil. We have yet to see whether the radical and apparently successful new devices can bring about any material improvement in the economic picture. If that can be done, and we wishfully hope that it may be possible, then these developments mark an important milestone in the advance of the circuit breaker art.

B. P. Baker: The authors are grateful to the discussers of this paper for their valuable contributions and pertinent questions. Table I of this paper shows the results of 18 interrupting tests at 132 kv on the single pole of a 138-kv compressed air circuit breaker. The current range was varied from 270 amperes to 8,900 amperes. The arcing time varied from 0.6 to 2.1 cycles and shows no tendency to become long at any particular value of current. There is however, as pointed out by Mr. St. Clair, a considerable variation in arcing time for any given range of current. At this particular value of voltage, that is 132 kv on a single pole of a 138-kv breaker, one-half of the interrupting element is not always able to interrupt line-to-line voltage, and thus the arc has to be drawn into the second orifice or other half of the interrupter. If the arcing time exceeds 1.5 cycles, it may be assumed that the second orifice is being called upon to render some assistance to the first one. It may be noted that at 132 kv approximately 70 per cent of the extinctions require only one orifice, while at 66 kv as shown in table II, 100 per cent of the extinctions were obtained by the upper orifice only. This, we believe, explains how at the higher voltages a single orifice may be expected to show limitation and eventually fail if the voltage is carried too high.

The modification of the circuit recovery rate by the asymmetry of the current was very small. This was due to the low power factors of the circuit and to the range of the asymmetry. The test 18 having 8,900 amperes at 123 kv and shown in figures 3 and 4, may be taken as an example. The asymmetry was about 35 per cent at the time of arc extinction, which occurred at the end of a large half-cycle. On a zero power-factor circuit 35 per cent asymmetry reduces the recovery rate only about 6 per cent due to the shape of the sine waves which change rapidly near zero and slowly near their crests. On a laboratory circuit having about ten per cent power factor the current zero normally occurs before the crest of the voltage wave. An asymmetrical wave shifts the zeros and the delaying of the zero after the large half cycle causes first an increase and then a decrease in the transient recovery voltage. In this particular test the 35 per cent asymmetry produced a reduction of only two per cent in the transient recovery voltage. Even if it had extinguished at the end of a small half cycle, the variation still would have been negligible—less than ten per cent. As this example is typical of the largest amounts of asymmetry obtained on tests reported in this paper, it shows why the cathode-ray oscillograms did not show appreciable differences between the circuit recovery rate and the recovery rate obtained on test.

Figure 8 is an oscillogram of the interruption of low current at 132 kv by 138-kv single-pole breaker. In this case the point of energizing the trip coil is indicated and shows a breaker time of $6^{3}/_{4}$ cycles from rise of trip coil current to parting of contacts. 1.2 cycles of this time is consumed by $1^{1}/_{2}$ inches of sliding motion in the finger contact before parting. A large portion of the remaining $5^{1}/_{2}$ cycles is used by the electropneumatic pilot valve. This valve is a standard railway control valve which was not designed for high speed. It is thus quite apparent that a large portion of the $5^{1}/_{2}$ cycles can be eliminated.

The relative cost of outdoor compressed air breakers and outdoor oil breakers is difficult to compare because of the air equipment required with the air breaker. However, comparing four compressed air breakers with three current transformers each and including one air system for the four breakers, we find that this combination is at least 25 to 35 per cent higher in cost than four equivalent oil breakers each with three current transformers.

A Conserved-Pressure Air-Blast Circuit Breaker for High-Voltage Service

Discussion and authors' closure of paper 41-58 by W. R. Rankin and R. M. Bennett, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 193–7.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper together with that by Messrs. Ludwig and Baker present two quite different arrangements of outdoor compressed air circuit breakers using modified nozzle-type interrupters and for similar voltage and service conditions. There is a value in having these two developments, which have been carried on in parallel, discussed at the same time before the Institute, since both will soon be placed in service on important utility systems, and the reaction of operating people to their design features will help determine a final type.

The writer wishes to suggest a trial period on a limited number of installations for the accumulation of operating data and experience. After a reasonable period a further discussion before the Institute should be valuable.

In securing such experience, the following points should be observed as they bear on the selection of the most suitable type for American service.

1. Arrangement of disconnecting switch. Some form of disconnecting switch is necessary on all types of compressed air outdoor breakers suggested to the present time. The form showed by Rankin and Bennett is possibly better adapted for weather protection than some others. The form showed by Ludwig and Baker affords a definite mechanical interlock between the interrupter and the disconnecting switch unit. Other forms of disconnect are being studied and it is quite possible an alternate form will be found most serviceable.

2. Insulation characteristics. These breakers rely on air columns between line potential and ground continuously which have internal surfaces that are not corrugated and not glazed. The integrity of this internal surface under such conditions of temperature and moisture as will obtain with outdoor compressed air breakers is of vital importance. This has reference to 60-cycle test values and impulse characteristics. The impulse characteristic of the interrupter unit itself during the short period of time to which it is subjected to line voltage after interruption must be carefully considered.

3. The usability of insulating materials for outdoor interrupters when subjected to moisture and arc products requires further confirmation. This appears a fertile field for research on the special types of insulation materials required.

4. The conditioning of the air used both for circuit breaker operation and for interruption is a matter of some concern. Will it be necessary to bleed a trickle of warm air continuously through the interrupter or will properly dried and cleaned air from the compressor system be adequate when used in an interrupter subjected to the normal variations of surface moisture and temperature.

5. The most economical pressure for storage and breaker operation requires careful study. For indoor equipment storage at 250 pounds with breaker operation at 150 pounds appears adequate. Higher pressures are indicated for outdoor work, possibly 1,000 pounds storage and 300 pounds utilization.

Present oil circuit breakers of all large manufacturers are now of generally the same type, the principal differences are in the interrupter units. This condition has come about through a process of selection of desirable features over a period of years. A similar selection will take place with respect to these new compressed air devices, but time will be necessary to assist a proper selection.

It is gratifying that the large utilities as represented by their joint committee members are willing to proceed on a reasonable schedule of ratings for an experimental period. This method will result in rational development expenses to manufacturers and the accumulation of necessary field experience with a minimum of trouble to operators.

Because of overoptimistic statements regarding possibilities of cost reduction for air circuit breakers over conventional oil types, the writer wishes to caution that the perfection of new devices frequently adds features not thought of at first. Even in oil breakers many of the elements of costs have been introduced in the past few years due to the demand for perfection in service and reduced maintenance. In my opinion a perfected air breaker design will cost as much or more than a corresponding oil breaker up to 115 kv and possibly up to 138 kv, even when both types are produced in equal quantities. For voltages above 138 kv the newer form should have definite cost advantages.

The outdoor compressed air breaker has certain inherent advantages which make it desirable to a system operator. These include: High speed, both during opening and closing; short interrupting time; and probable reduced maintenance time. Present oil breaker apparatus, however, is entirely satisfactory and American system operators will not accept new equipment unless it possesses all the advantages of present products. This makes it vital that compressed air breakers for outdoor service be perfected to a high degree before an effort is made to secure a broad market for them.

J. Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): I wish to congratulate the authors for the simple method they have found for increasing the voltage interrupting rating of air-blast circuit interrupters. I wish to congratulate them also for not attempting to give any simple detailed quantitative theory of their breaker. There probably is no detailed quantitative theory that is correct and also simple.

Particularly I wish to congratulate the authors for completely omitting any reference to the so-called displacement theory as applicable to their breaker. Even more, I must congratulate the authors for their obvious courageous disbelief in this theory even if unexpressed in their paper, since the devices which they used and found successful are such for which the displacement theory would certainly predict failure.

In late years, my role as a discusser at these switch-gear sessions has frequently been as an exposer of the unwarranted pretensions of this displacement theory. Perhaps then I may be permitted to explain in more detail how the improved devices described by the authors completely contradict the displacement theory.

According to the displacement theory, at the final current zero a thin layer of dielectrically sound fluid interposes itself across the arc column and grows in thickness at a rate determined by the fluid velocity. As it increases in thickness, its total dielectric strength also increases, being given by the product of its thickness and its intrinsic dielectric strength per unit length. If its total dielectric strength at each moment exceeds the rapidly rising voltage impressed on it by the circuit, the arc cannot reignite.

In this displacement theory, the thin growing layer bears the whole circuit voltage. The rest of the arc plays no part in the interruption, and its loss of conductivity during the interruption process is negligible. It is meaningless to talk of its breakdown during the interruption process, since it is broken down and stays broken down for a period of time which is long compared to the actual time of arc interruption.

In the particular case discussed here, the fluid velocity is not changed by the devices added by the authors. Neither, according to the authors, is the density of the fluid at the place where the interrupting layer would form. Hence the dielectric strength of the interrupting layer and its rate of growth must be unchanged, and therefore no improvement in interrupting capacity can result from the devices added by the authors. There is no point in increasing the normal dielectric strength of the arc space outside the interrupting layer, since, according to the displacement theory, this space is already as completely broken down as it can be at the moment of arc interruption, and its normal dielectric strength is of no consequence.

I take it then that the authors must believe that a considerable length of the arc must take part in the actual interruption process, since they themselves say that the modifications which they have made do not affect the conditions at the nozzle where the displacing layer would form, but only the remote parts near the moving electrode. How this longer length of arc is made to recover its dielectric strength so quickly by the gas blast is an interesting theoretical problem. Perhaps my suggestion of an enhanced diffusion by turbulence may be helpful.

J. R. North: For discussion, see page 673.

H. P. St. Clair: For discussion, see page 673.

D. C. Prince: For discussion, see page 671.

W. K. Rankin and **R. M. Bennett:** As Mr. North points out the elimination of fire hazard was a major objective in the development of oilless interrupters for indoor service but is of less consequence where outdoor equipment is concerned.

Experience that has already been obtained by the application of the air-blast principle to medium voltage indoor breakers, indicates that there are certain other inherent advantages in the air-blast interrupter that can be made available in outdoor breakers.

As indicated by Mr. MacNeill the air-blast circuit breaker suffers no deterioration of the insulating and interrupting medium so that maintenance is required only by contacts and interrupter parts. Both field and test experience shows the deterioration of these parts to be remarkably light even at the highest currents.

The authors believe that these other advantages alone justify the development of high-voltage air-blast circuit breakers.

Dr. Slepian's conclusion regarding the effect of the conserved pressure chamber on the rate of growth of the insulating medium after interruption is correct. In short, the addition of a conserved pressure chamber to a short nozzle interrupter did not affect the ability of the breaker to interrupt high rates of rise of recovery voltage. However, as has been shown, the short nozzle failed at high voltages, and its failure was not related to recovery rate.

As the blast pressure of the short nozzle is reduced, the breaker continues to interrupt the circuit momentarily, but progressive dielectric breakdown results in restriking of the current as much as a half cycle or more after the initial interruption. Now deionization and displacement are completed in a few milliseconds at most so that the addition of the conserved pressure chamber had nothing to do with displacement, nor deionization but rather was for the purpose of preventing this progressive breakdown of the contact path after interruption.

The conserved pressure chamber described in the paper uses a spring-loaded valve to control the pressure. At heavy currents where larger volumes of ionized gas are produced this valve opens wider than at light currents. However, provided the maximum current to be interrupted by such a circuit breaker produces volumes of ionized gas that are small as compared with the volume of the main air blast, a simple restriction in the exhaust passage is sufficient to hold the pressure within reasonably close limits and the spring-loaded valve may be eliminated.

Editor's Note—Correction: The untimely death of Mr. Rankin prevented the making of desirable corrections in the Rankin-Bennett paper prior to its publication on TRANSACTIONS pages 193–7 (May section). Mr. Bennett subsequently made available the following corrections:

1. Page 194, column 1, line 5—The statement ". . . . at 38-kv . . . ." should read ". . . . at 88-kv . . . .".
2. Page 194, figure 4—The ordinate scale now reads "Kva = EI/1000" should read "Kva/1000".
3. Page 194, column 3, line 22—word "minimum" should be "maximum."

The Geometry of Arc Interruption

Discussion of paper 41-61 by E. W. Boehne, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 524–32.

J. Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author has done an interesting piece of work in calculating the course of the current in a circuit involving an arc when the arc voltage is known. There are, however, a number of implications given with which issue might be taken.

First is implied that there is some advantage in a high arc voltage, so that the designers of the switch under discussion actually designed to obtain a high arc voltage. A more rational objective to my mind is to design to obtain an interruption as quickly as possible, and with as low an arc voltage as possible. It so happens that by means of the magnetic blast it is as yet not possible to interrupt the circuit with a low arc voltage. Dickinson and Nau in their paper describing a similar breaker, show quite as high arc voltages at corresponding instantaneous currents as Boehne. These gentlemen, however, do not make a virtue of this, but are quite content that the circuit is quickly interrupted.

It is true that with a high arc voltage the magnitude of the oscillating transient at current zero may be reduced, because the current zero does not occur at the moment of peak open circuit voltage. However, with this type of switch the leakage at current zero is so great that the oscillatory transient hardly develops at all, as Boehne points out in his cathode-ray oscillograms—figures 12, 13, and 14. One can hardly take credit for moving away from voltage peak a transient oscillation which does not take place at all.

But is this oscillatory transient which would occur at final current zero with a low arc voltage breaker so much to be feared as to make it preferable to dissipate quite large amounts of energy in the breaker to prevent it? Of course not. First of all, if we could make a low arc voltage breaker of similar size and cost, we would much prefer to use it and take care of the transient if we cared to by other means such as a shunt resistor with trifling energy dissipation. But actually we would do nothing about the transient because all apparatus in our actual system is built to withstand it. When the switch closes upon a piece of apparatus at peak voltage, this same transient appears and must be withstood. Why worry about it, then, if this transient occurs when the switch opens?

The fact is that at the moment we are not able to make a low arc voltage switch of comparable rating size and cost, and that is really why the arc voltage is high.

A superficial reading of the paper by Boehne might leave one with the impression that the course of the current in a circuit using the switch in question can be calculated in quite complete detail. This, however, is not at all the case. The arc voltages are not determined beforehand, but need to be taken from an oscillogram. Since that oscillogram also gives the current, voltage, and watts directly, the calculation serves to give one the satisfaction of verifying that linear circuit theory is valid for the rest of the circuit.

The implication is given in the paper that the particular arc chute pictured in figure 15 has some special virtue in producing a high arc voltage. It is true that for a given position of the arc its sinuous length is much greater than the straight distance between the horns. However, the voltage of an arc depends on many factors besides its actual length. In the switch here considered there is a strong transverse magnetic field blowing the arc up into the chute. If it were not for this magnetic field the arc would rise very little into the chute, and only a low voltage would be produced in spite of the sinuosity. It is because this transverse field produces mechanical forces upon the gas in which the arc is playing, and moves this gas upward that the arc moves upward into the chute. The arc moves up into the chute because if it stood still its arc voltage under the gas blast through it produced by the magnetic field would be higher than its arc voltage when moving with the blast into the chute.

However, the mechanical force of the field upon the arc is given by the *straight* length between horns, and not the sinuous length. One would expect then, that about the same arc voltage will be obtained for a given magnetic field and given distance between horns if similar sufficient impediment is placed in the chute to retard the upward motion of the arc in similar degree, regardless of whether this impediment involves impressing a sinuosity on the arc or not. This thought is supported by the fact that Dickinson and Nau show comparable arc voltages in their switch where the arc is driven by a magnetic field into a narrow slot with no sinuosities.

R. H. Nau (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In the paper on "The Geometry of Arc Interruption," as well as at two previous Institute meetings, considerable attention has been given to the virtues of current suppression as a function of breaker performance. For the second time the circle diagram and lemon-shaped wattage trace have been given to explain the mechanism of current suppression as advantageously used in arc extinction. During arc interruption the electric circuit is transiently disturbed, and the conditions cannot be represented by the elementary steady-state relations of an a-c circuit as expressed by the circle diagram.

Mr. Boehne attempts to demonstrate that the "Magne-Blast" breaker relieves the circuit of overvoltages, and produces relatively low arc energies. He, however, avoids discussing certain recovery voltages and energies which are found in the oscillograms of figures 12, 13, and 14. At the end of the so-called "loop 1," of figures 12*a* and 13*a*, actually second current loop following the parting of the contacts, recovery voltages (e_r) of more than twice the maximum cir-

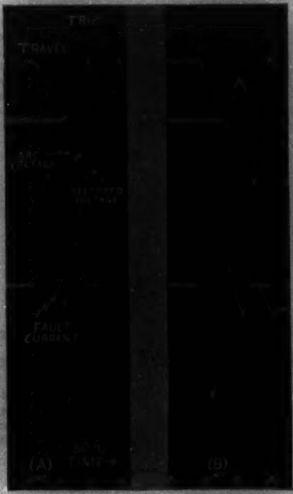

Figure 1. Current interrupted, 40,000 amperes; restored voltage, 4,020 volts

cuit voltage occurred. Note figure 7. It is evident that a short time was required for the arc to move from the parting contacts and into the arc chamber; however, during the so-called "loop 1" the arc had risen high into the arc chamber, dissipating considerable heat energy. At the end of "loop 1" of figures 12*a* and 13*a* interruption should have occurred, but the recovery voltages rose to values approaching twice the circuit voltage and caused the arc to re-establish. The only apparent advantage that exists in a low recovery voltage, as at the end of "loop 2," is the protection given to the "Magne-Blast" breaker itself during short-circuit operation. Magnetic oscillograms taken on the "Magne-Blast" breaker clearly show that there is no tendency to reduce the recovery voltages following interruption of currents below several hundred amperes.

The total energy dissipated in the arc chamber of the "Magne-Blast" breaker seems to be considerably greater than that expected of modern interrupters. From the data given by Mr. Boehne, the heat energy evolved is 0.73 watt-hour per megavolt-ampere for figure 12*a;* 0.85 watt-hour per megavolt-ampere for figure 13*a;* and that for figure 14*a* is 0.57 watt-hour per megavolt-ampere.

An inspection of oscillograms taken with a 5-kv 250,000-kva magnetic "De-ion" breaker reveals that less than two actual current loops are encountered during high-current interruption. The arc energies of these two representative oscillograms are 0.21 and 0.15 watt-hour per megavolt-ampere, respectively. These data definitely indicate that the total heat energy liberated in the "Magne-Blast" breaker is 2.7 to 5.7 times that encountered in the magnetic "De-ion" breakers. It seems very likely that this increased arc energy will hinder the "Magne-Blast" breaker if it is operated on severe duty cycles.

The "Magne-Blast" breaker was first publicized as having an interrupting rating of 100,000 kva at 2,500 and 5,000 volts. In Mr. Boehne's paper he now states that by taking advantage of principles whereby arc resistance is increased to suppress the current from its normal value an interrupting rating of 250,000 kva is obtainable. However, he does not make clear what design features have made this improvement possible.

D. C. Prince: See discussion, page 671.

A Construction Theorem for Evaluating Operational Expressions Having a Finite Number of Different Roots

Discussion of paper 41-37 by P. C. Cromwell, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 273–6.

E. Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): The so-called "construction theorem" of the author represents a valuable simple method to extend the direct operational method to asymptotic solutions which heretofore could be obtained in complete form only by using the theory of functions of a complex variable. One of the most impressive examples is the application of a unit voltage to an infinite cable with terminal inductance. Using the infinite integral form of solution, J. R. Carson[1] also demonstrated how the infinite series part of equation 31 can be obtained by direct asymptotic expansion, but the method fails to give the first two terms of 31 which are quite essential. Professor Cromwell has shown that it is only by using the differential operator p consistently for all the factors arising in the denominator that one can get the complete solution. His formulation of a principle comparative to the "expansion theorem" but based entirely upon the process of differentiation eliminates an obvious weakness of the elementary approach to operational methods.

D-C Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures

Discussion and author's closure of paper 41-9 by J. G. Trump, F. J. Safford, and R. W. Cloud, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 132–5.

Wm. C. Brenner (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): I was very much interested to see the results published in this excellent paper because I have recently been connected with the determination of the breakdown strength of air between spheres over a range of pressures greater than those given in this paper and for much smaller spacings.

The interesting point that I wish to bring out is the fact that an empirical equation determined from the work of H. H. Skilling and myself fits the experimental values presented in both papers with equal precision. The equation and its range of application may be seen in the discussion of the paper: The Electric Strength of Air at High Pressure—II, H. H. Skilling and Wm. C. Brenner [AIEE Transactions, volume 60, 1941 (March Section), pages 112–14].

J. G. Trump: Compressed gases are now being used with advantage for the insulation of high-voltage X-ray generators, high-frequency condensers, and to some extent in switches and in cables. It seems reasonable that gases at high pressure will become of increasing importance in other types of high-voltage power apparatus. Of the four media available for the insulation of high voltages—solids, liquids, gases, and vacuum—the latter two, gases and vacuum, have been least investigated and appear to offer the greatest possibilities for the future.

The use as insulators of condensable gases such as Freon introduced some special problems. Since Freon saturates at 85 pounds per square inch absolute and 70 degrees Fahrenheit, the temperature of this gas must be raised in order to prevent condensation at higher pressures. While it is evident that the density of the gas does not increase directly with the pressure when the temperature is caused to increase, the actual departure from a linear relation between pressure and density was only about two per cent and was least at the high-pressure end of the investigated range. Since engineers are concerned with actual pressure rather than calculated density of the gas, the breakdown curves for Freon were drawn with absolute pressure as the independent variable.

I was pleased to note Mr. Brenner's statement that the electric strength of air, as determined in his investigation at voltages up to 60 kv, checks closely with that which we have observed at still higher voltages. Such agreement is usually difficult to obtain, since the breakdown strength is strongly dependent upon factors such as the electrode surface condition, area, and geometry, which are apt to vary in different investigations. The nature of the metal itself is not as important as the surface smoothness and the extent of the surface contamination which is inevitable in a gas-filled gap. We have found, as did Professor Skilling and Mr. Brenner, that repeated sparkover is the most effective manner of "conditioning" the electrodes. Sparkover with excessive energy, however, will roughen the electrode surface and may reduce the voltage which can be insulated. We have observed that the maximum voltage which can be readily obtained under given conditions of pressure and field geometry is less when the area of the electrode is large. This is probably caused by the increased difficulty of approaching ideal conditions over large areas. It may be estimated that the effective area of our interelectrode gap was about a hundred times that of Professor Skilling. Considerations such as these must be taken into account by engineers interested in applying high-voltage data taken on small electrodes to large apparatus.

While the physical understanding of the breakdown mechanism in gases at high pressure is closer to the truth now than it ever was, it seems to me that attempts to describe accurately this complicated breakdown phenomenon in terms of the physical constants of the gas and electrode system must of necessity neglect many of the influential breakdown factors. The situation in a gas-filled gap at the moment when conditions are ripe for a cumulative discharge is remarkable for its complexity. There are present a statistical number of molecules in various states of excitation and ionization with many ion-producing mechanisms contributing to this condition. The gas itself has many physical properties which affect the process, and indeed the gas is usually a complex mixture of different molecules. Recombination is constantly taking place with low probability in the gas, with enhanced probability at the electrode surfaces. The electrodes are contributing to the discharge by photoelectric emission, by secondary emission due to positive-ion bombardment, and by high field emission. These mechanisms have been quantitatively examined separately by careful physical research in high vacuum with thoroughly outgassed electrodes. In a gas-filled gap these mechanisms are taking place together. The electrode surface is covered by many molecular layers of contaminating material which obscures the emission characteristics of the metal itself. The electric field, which may be uniform or of some other geometry because of the shape of the electrodes, is profoundly affected by both the general space charge in the gap as a whole and by the dynamic localized space-charge concentration in the region of electron avalanches. The gap is being irradiated by radiations from naturally radioactive materials and cosmic rays. In spite of this complexity, it is possible and desirable, to understand the role which the several processes play in the general picture of breakdown and many valuable contributions to this phase of the insulation problem have been and are being made.

The Electric Strength of Air at High Pressure—II

Discussion and authors' closure of paper 41-21 by H. H. Skilling and W. C. Brenner, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 112–15.

G. C. Nonken (General Electric Company, Pittsfield, Mass.): The work of Dr. Skilling and Mr. Brenner is a distinct contribution to the field in presenting fundamental data on the strength of air at increased pressure.

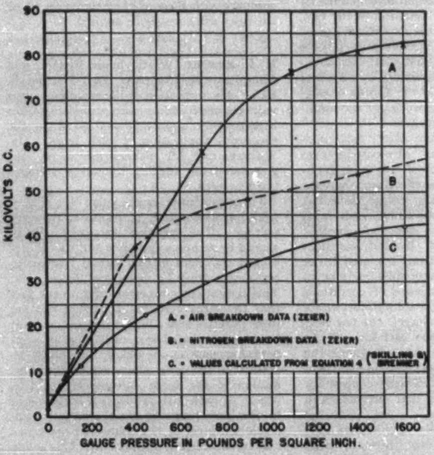

Figure 1. D-c breakdown of 15-millimeter spheres spaced at 0.4 millimeter

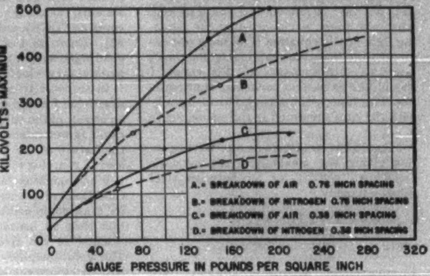
Considering the wide spread of the data published by various authors on the dielectric strength of high-pressure gases, it is remarkable the close check between the authors' data and that of A. H. Howell.

The authors do not try to explain the phenomena characterized by the sparking voltage of the first few sparks which are lower than the final stabilized sparking voltage. Maybe this behavior could be accounted for by the possible presence of dust or foreign particles settling on the spheres and lowering the spark-over voltage. A few sparks would burn or force the particles away. H. H. Race[1] showed how small insulating or conducting projections on sphere gaps appreciably reduced the spark-over voltage. His data showed that a piece of insulation, projecting from the sphere $2^1/_2$ per cent of the sphere spacing, decreased the 60-cycle flashover to one-half its normal value and that a very small hemispherical bump on a plane electrode will theoretically increase the gradient at that point to about three times the average gradient between the plane electrodes.

Figure 2. 50-cycle breakdown of concentric cylinders (Finkelmann)



The authors' equation 4 matches Mr. Howell's data remarkably close. It is not quite clear to the writer why the authors chose to describe their data of figure 4, which are plotted as straight lines, with equation 4, which is the equation for a curved line.

If electron emission is responsible for the characteristic drooping curve of sparkover with pressure, the shape of the spark-over curves for different gases should be the same if the same electrodes are used. Figure 1 shows spark-over data by O. Zeier.[2] The tests were made with 15-millimeter diameter steel spheres with a d-c voltage. These data are for smaller spacings and include much higher pressures than those of the authors. The curves for air corresponding to the authors' equation 4 are considerably lower in voltage than Zeier's curve for air but they have somewhat similar shapes. The data for the sparkover in nitrogen show a rapid drooping off in voltage with increase in pressure; in fact the curve calculated from curve 4 checks much closer to the nitrogen curve than it does to the air curve.

Figure 2 shows somewhat similar data by Finkelmann[3] except that the sparkover is between concentric cylinders with a 0.76-inch spacing and 0.38-inch spacing between cylinders and the tests were made with a 50-cycle per second a-c voltage. These data also show the spark-over voltage with nitrogen is about the same as that of air at atmospheric pressure but that the sparkover in nitrogen increases less rapidly than in air with increased pressure.

It may be drawn from these data that some factor other than electron emission causes the nitrogen curves to droop more than the air curves. These comparisons do not prove the absence of an electron emission effect, but they do convey that if there is an electron emission effect due to different electrode materials, it is secondary to the effects due to different gases.

Wm. C. Brenner: In response to G. C. Nonken's printed discussion, I should like to say that the choice of an equation giving a curved line to represent the linear data presented for steel electrodes in figure 4 resulted from the assumption made in writing equation 2. Though some had claimed at the winter convention at Philadelphia that this assumption was oversimplifying breakdown theory, the fact remains that the resulting equations (modifications of Paschen's law) agree reasonably well not only with our own data but that of references 5 and 6 as well, whence it might be claimed that the resulting form of the equation is perhaps one degree better than that expressing Paschen's law. In substantiation of this claim, I should like to note in particular that equation 3 for brass electrodes checks identically with the data presented in the curve, figure 3.

I should like to include an alternate equation giving the maximum crest kilovolts breakdown voltage for air between steel spheres, namely

$$V_m = 53.6 \times (P+1.36) \times S + 0.5$$

where

V_m = maximum attainable kilovolts (a-c crest or d-c)
P = absolute pressure in atmospheres
S = gap spacing in inches

This linear equation is purely empirical and was made to fit (even more closely than equation 4) the data collected for the breakdown of air between steel spheres for the range of pressure and spacing as shown in figure 4. If one is willing to accept the equivalence of a-c crest kilovolts to d-c kilovolts, it is interesting to note that when using the above equation (and it is to be noted that there is only very little difference to be found between the use of the above equation and equation 4 of the paper) the predicted breakdown voltages for gaps up to 1.2 inches agree very closely with the results given in the paper "D-C Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures" by J. G. Trump, F. J. Safford and R. W. Cloud [AIEE Transactions, volume 60, 1941 (March section), pages 132–4].

In light of the very close agreement of the above equation with the experimental data for the maximum crest kilovolts breakdown strength of air between steel spheres for both experimental ranges considered, I should be willing to use the equation (with appropriate safety factors* depending on the application) for various design purposes. Although the above equation has only been checked over a range in which the value of V_m was below 1,000 kv, P between 1 and 21 atmospheres, and S between 10 mils and 1.2 inches, it is not my wish to imply that it holds only within these limits, but it is hoped that further checking of experimental data may prove the usefulness of the equation for even wider ranges of pressure and spacing.

H. H. Skilling: The data presented by G. C. Nonken from work by Zeier and Finkelmann are quite interesting, particularly in comparison with the results of Buehl (reference 6 of paper) and of Trump, Safford, and Cloud, respectively, with which they do not agree very closely. In so far as the results are comparable with the results of the present authors, our work tends to agree with Buehl and with Trump, Safford, and Cloud, as well as with Howell (reference 5 of paper) and with Goldman (Breakdown of Compressed Nitrogen in Small Gaps, Comptes Rendus (Doklady) de l'Académie des Sciences de l'URSS, volume 18, 1938, pages 89–94). Equation 4 of the present paper gives good agreement on the whole with the experimental work of these latter investigators.

In response to another paragraph of the discussion I would like to attempt to clarify an aspect of the subject that seems likely to result in misunderstanding. This relates to the nature of the ionization processes that lead to sparking in a gas.

When sparking takes place under normal conditions of pressure and temperature, as for example in ordinary air, it is an indication that an unstable condition has been reached in the space between electrodes. The great majority of ions and electrons that carry current in the interelectrode gap at the moment preceding sparking are produced by impact ionization by electrons. These electrons are themselves largely the product of earlier impacts. When the electric field is sufficiently intense the rate of production of electrons becomes almost unlimited and a spark results. This is the condition that Townsend assumed to correspond to an infinite production of electrons.

Although the production of free electrons is largely due to impact ionization, this process alone could not be self-sustaining. A few electrons must be produced at or near the cathode by some other cause. It is probable that at atmospheric pressure this other cause is either irradiation of the cathode by ultraviolet light that results from electrical action taking place in the interelectrode gap, or bombardment of the cathode surface by positive ions, or a combination of the two, possibly complicated by ultraviolet ionization of the gas itself. Whatever the process at or near the cathode that makes the ionizing mechanism self-sustaining, it is evident that any disturbance of the supply of electrons from the cathode will alter the conditions for sparking in the gas.

It is in this connection that "field emission" or "cold emission" of electrons from the cathode as a result of extremely high-voltage gradients can be effective. One cannot expect that a gradient will be reached at which sparking will suddenly result from field current, whereas it previously resulted from impact ionization. Instead, the effect of a relatively few electrons liberated at the cathode by field emission will merely be to disturb the delicate balance of conditions that exist in the gap at a voltage just under the normal sparking voltage; the few electrons released from the cathode will be vastly multiplied by impact ionization in the gas, and the result of field emission will be a slight lowering of the voltage required for that unstable condition that culminates in sparking.

Consequently it is only natural that a reduction of sparking voltage below the value predicted by Paschen's law should be dependent upon the gas as well as upon the electrode material, even though it be assumed that field emission from the electrode is the cause of this lowering of voltage.

---

* The safety factor is assumed to apply in every case to the threshold value V_t below which sparking should not occur irrespective of time, where the value of V_t is given by the relation

$$V_t = 0.90 \times V_m$$

Control of the Switching Surge Voltages Produced by the Current-Limiting Power Fuse

Discussion and authors' closure of paper 41-60 by E. A. Williams, Jr., and C. L. Schuck, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 214–17.

J. A. Elzi (The Commonwealth and Southern Corporation, Jackson, Mich.): High-speed circuit-interrupting devices of all types introduce new problems in switching surge voltages. If these surge voltages cannot be limited, it will of course be necessary to take them into consideration in station and equipment designs. The most desirable procedure is that of limiting the surge voltages in the design of the interrupting devices itself as has been done in this case.

In setting up the conditions which determine the allowable magnitude of surge voltage, the authors have expressed the limiting conditions in terms of 60-cycle phenomenon. The oscillograms presented in figure 4 indicate that the arc voltage does not have a particularly steep front, but is of course of a transient nature. This would seem to indicate that the limiting conditions as set up are of the right order and should prove to be satisfactory if the characteristics given in figure 4 are typical.

As shown by equation 1, the transient voltage is effected by the inductance of the external circuit. It would seem important to know how the characteristics of the test circuit used in obtaining the oscillograms compare with those of the circuits on which the fuses will actually be applied.

H. L. Rawlins (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The limitation of the switching surge voltages produced in current-limiting fuses is extremely important and vital to the successful application of such fuses. Mr. Williams and Mr. Schuck are to be congratulated for limiting the surge voltages in their fuses.

I question, however, the value of $\sqrt{2}(2E+1{,}000)$ as a safe limit of transient recovery voltage. The transient recovery voltage should be as low as possible and should not exceed the peak of the normal frequency-recovery voltage by more than 25 per cent. This limitation is necessary due to the fact that the surge voltages of current-limiting fuses in series add. With a line-to-line fault on an ungrounded system having an accidental ground on one phase, the voltage to ground on the other phase will be the summation of the surge voltages of the two fuses. If each fuse produces a surge equal to the limit proposed by the authors, the insulation level of the connected machines may be exceeded by 100 per cent. This is not true in the case of circuit breakers or other types of fuses in which circuit interruption occurs at normal current zero, and the transient recovery voltage is a function of the circuit rather than the interrupter.

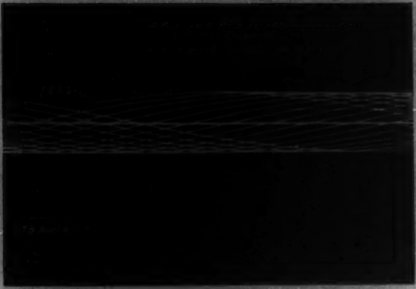

Figure 1

Figure 2

It is possible to make a current-limiting fuse with a very low value of transient recovery voltage. At the Cincinnati District meeting in October, we announced a new type of current-limiting fuse having a positive voltage-limiting action [AIEE TRANSACTIONS, volume 60, 1941 (February section), pages 77–9]. At that time, tests had been limited to 20,000 amperes at 13.2 kv. Since then, tests have been extended to over 100,000 amperes at 13.2 kv and 70,000 amperes at 22 kv. In no case has the transient recovery voltage exceeded the peak of the restored voltage by as much as 25 per cent.

Figure 1 shows the interruption of 86,500 amperes at 13.2 kv (by a 15-kv fuse of the new type). The current was limited to 470 amperes with a follow current as shown. The voltage surge was limited to 16 kv as shown on the cathode-ray oscillogram at the top.

The top cathode-ray oscillogram of figure 2 shows a 15-kv conventional current-limiting fuse interrupting 45,000 amperes at 13.2 kv. The voltage surge rose to a very high value of 58.5 kv.

The lower cathode-ray oscillogram of figure 2 shows the interruption of 69,000 amperes at 22 kv by a 23-kv fuse of the new type. The voltage surge was limited by the voltage-limiting element to only 32.6 kv.

C. L. Schuck and E. A. Williams, Jr.: The authors greatly appreciate the discussions presented and feel that they make for a more thorough understanding of the factors contributing to both the design and application of the current-limiting power fuse.

Mr. Elzi asks a question which has probably occurred to many operating engineers, regarding the test circuit used, and how its characteristics compare with those of circuits on which the fuse is to be applied. A complete description of the test circuit and measuring equipment is given in the article "High-Power Interrupting Capacity Testing Station of the General Electric Company," by G. F. Davis, appearing in the *General Electric Review* for February 1932, pages 99 to 106 inclusive. The generator is rated 100,000 kva and can deliver over 1,000,000 kva, including the d-c component, on three-phase short circuit.

In making interrupting tests on fuses, the most severe testing conditions were deliberately sought, especially in accumulating the data on voltage surges. During interrupting tests, through the complete range of currents between the minimum melting current of the fuse and station capacity, the current was limited by air-core reactors and generator impedance. Most of the short-circuit tests were made without any impedance external to the generator, with only short lengths of bus and cable for making the necessary connections. It is therefore felt that the test conditions were somewhat more severe than those usually encountered in the field, since there is usually line impedance between the generator and the fuse.

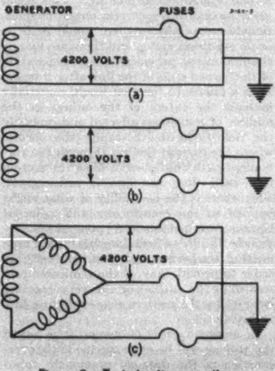

Figure 3. Test circuit connections

Mr. Rawlins' suggestion of the possibility of a ground developing in an ungrounded system, followed by a pure line-to-line fault on the far side of the fuses from the ground appears rather remote. In practice, grounds develop on one line of ungrounded systems quite frequently, but a subsequent fault on one of the other lines is usually also to ground. Table I gives the results of tests made single phase and three phase at 4,200 volts, using fuses rated 5,000 volts. The available short-circuit current in these tests was 86,000 amperes. It will be noted that the transient recovery voltage for tests involving only one fuse is in general higher than any obtained in the tests involving more than one fuse. The recommended limit for fuses of this voltage rating, based on motors rated 4,000 volts, is

$$v = \sqrt{2}[2(4{,}000)+1{,}000] = 12{,}700 \text{ volts}$$

The Protective Link

Discussion and authors' closure of paper 41-59 by J. K. Hodnette and M. G. Leonard, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941 (May section) pages 226–9.

G. F. Lincks (General Electric Company, Pittsfield, Mass.): When a transformer with a protective link is connected onto a distribution circuit it becomes a unitary part of a whole co-ordinated overcurrent protective system from the service entrance fuse on the consumer's meter board to the relays at the generating station. This is true whether such co-ordination is predetermined or just the result of "happenstance." Service on a major part of the system may be disrupted for a long time due to a misapplication or any false operation of the protective link just as it would with any other associated apparatus. Extensive co-operation with operating engineers in all parts of the country on studies for improving overcurrent protection and service continuity has indicated that proper application demands the ready availability of factual data on all protective apparatus especially as to:

1. Melting time-current characteristics, preferably plotted in accordance with EEI-NEMA approved practices.[1]

2. Total clearing time-current characteristics.

3. How accurately these published characteristics can be maintained in commercial production and in service.

4. The reliability of operation in clearing fault currents over the full range from the lowest to the highest.

5. A definite current interrupting rating which can be met with any size of protective element made available for use in the device so rated. (According to AIEE practice this is expressed in rms amperes initial in arc for specified voltages.)

Renewable fuse links for expulsion fuse cutouts have been developed with an accuracy approaching the high standard set by the overcurrent protective relay with which they are associated. This has made possible the many benefits from the co-ordination of externally mounted fuse cutouts and fuse links connected in series with other fuse links and with relays on distribution systems. In the application of the protective link it is imperative to know whether the same high standard of accuracy and reliability of the associated external fuse links and relays is being provided and maintained. This is especially true since the protective link and its associated internal breaker by their very nature take up an unusually large share of the range available for all overcurrent protection on distribution systems.[2] Also field experience has shown that due to inadequate data as to what size of a link is in what transformer it has been necessary in co-ordinating such protective links with other apparatus to consider them on the basis of the worst conditions, namely, the longest time-current characteristics that have ever been applied. This is true even though some of the more modern protective links have been decreased in size so as to present much more of a hazard as to being blown by lightning.

In the paper the authors describe a method for changing the normally faster time-current characteristics of a fuse link when submerged in oil. This steeper characteristic is due to the convection currents in the oil carrying heat away from the fusible wires. At the lower currents where the melting time is sufficient to make this effective in increasing the heat dissipation, it tends to increase the currents at which a certain size of fusible wire melts in a given time. At the higher currents the effect decreases until the heat dissipation from this fusible wire is negligible during the very short melting time. Then the characteristics of the fuse in oil approaches that of the same fuse in air. Shielding the fuse by a tube retards or prevents the convection currents in the oil surrounding the link and thus makes its melting time-current characteristics approach that of a fuse in air. The authors claim to go one step further, combining the 1,083-degree centigrade melting temperature of copper with the blanketing of a surrounding fiber tube to distill gases from the oil. By so doing they claim they secure the slower time-current characteristics of their curve figure 3*c*. Similar characteristics in fuse links for mounting in the oil of distribution transformers are available using tin fusible wires with a 232-degree centigrade melting temperature which is well below the 275-degrees centigrade charring point of fiber. These desired time-current characteristics are provided by using the same design methods that have made possible the high accuracy of the external renewable fuse link. They can be secured with or without shielding the link by a surrounding tube. The authors' method introduces variables such as the distillation temperature, the energy required for distillation, and the possibility of trapped air above the oil in the tube which would totally void such predetermination as described and shown in figure 3. It would appear that these variables may make it impossible to meet the demands of modern overcurrent protection practices for accuracy and reliability.

The authors' discussion of interrupting requirements indicates little theoretical need for high-current interrupting ability but recommends applying the protective link on the basis of maximum available line short circuit. Their field experience corroborates their recommendations evidently due to internal line-to-line or line-to-ground breakdown caused by lightning surges or inadequate overvoltage protection. A large portion of the paper deals with the high kilovolt-ampere interrupting abilities without definitely tying them up to any of the specific types shown in figures 2, 6, and 7 and without reference to rms amperes initial in arc at specific voltages which is the approved AIEE, EEI, and NEMA method for rating fuses. The interrupting function of fuses at different voltages is not always directly proportional to such a kilovolt-ampere rating as is used in the paper.

While the paper deals largely with the maximum interrupting ability it clearly points out that if the link is permitted to do what it is supposed to do, namely, disconnect only winding failures, the majority of fault currents will be very low. Successful low-current operation is accredited to the use of a small auxiliary fiber tube. Such a tube would be precarbonized by the close proximity to the white hot copper link for a second or more before melting. This would make successful low-current operation questionable especially as there would be little or no expulsion action and there are no mechanical means provided to cause separation of the burned ends of the link after it melts. Such a failure to function would materially increase the extent of the outage in the number of consumers affected and probably the time to locate the faulty transformer where the current flowing through the carbonized path continues to blow the section fuse each time the line is re-energized. Then there is the possibility of what might happen to the transformer and adjacent equipment or persons. As pointed out previously, the use of fusible metals having high melting temperatures is not necessary in order to provide any of the requisites prescribed by the authors or the very exacting ones set by the modern renewable fuse link and relay.

In answering this discussion it is hoped the authors will be more specific in the presentation of the data as previously tabulated, tying it up definitely with the voltage and kilovolt-ampere ratings and the types of the transformers in which the different types of protective links are actually employed.

1. Both EEI and NEMA have standardized on the use of one size curve sheet for plotting the time-current characteristic curves of fuses. This is carried by Kueffel and Esser, New York., under No. 28962.

2. TRENDS IN DISTRIBUTION OVERCURRENT PROTECTION. G. F. Lincks and P. E. Benner, AIEE TRANSACTIONS, volume 56, 1937 (January section), pages 138–52.

S. R. Smith, Jr., and C. R. Craig (Distribution fuse cutout section, General Electric Company, Pittsfield, Mass.): The authors have contributed a very interesting paper on a type of protective apparatus which, due to its important position in the overcurrent protective scheme on the distribution circuit, deserves more than passing study. There are several points not elaborated on sufficiently in the paper to permit a clear understanding of the operation of these devices. It is hoped that a discussion of some of these will lead to a better understanding of the protective link and its functioning.

These devices operate in transformer oil, a relatively noncompressible medium, with more or less violent "explosive action." Transformer tanks are not normally made to withstand high internal pressure. Small unit pressures can produce high mechanical stresses when the tank surface is large. It would appear of real value if data could be included as to the tank pressures developed.

The authors' explanation of the blanketing effect on the fusible element to produce curve *c* of figure 3 is of necessity based on the premise that the element is entirely submerged in the oil. In figure 2 no vent is shown at the top of the tube to allow trapped air to escape and vents were omitted in devices that have come to our attention. While a good part of the air could be absorbed by the oil in time, it would seem that a portion of the fusible element would be in the trapped air above the oil, which portion would determine the melting curve thus making the blanketing effect of the tube of no value in producing the results as described. Variations in the amount of air trapped would greatly affect the accuracy of the melting time-current characteristics.

Referring to figure 5, the authors state—

1. "The electrode travels approximately six inches during the arcing period."

4. "The electrode travels approximately eight inches through oil in the half cycle following the extinction of the arc."

With the method of mounting in actual use as shown in figure 1, the motion of the electrodes would seem to be considerably restricted by the lead insulation and adjacent parts. Are the above data intended to apply in such a case?

The paper states that with the present knowledge, major insulation failures from lightning have been practically eliminated and therefore, line-to-line or line-to-ground failures of transformers are uncommon. The usual fault condition described is of a progressive nature with sufficient winding impedance in series with the fault so that the current does not approach system short-circuit proportions. However, under "Field

Experience" it is brought out that in most cases the lower electrode was violently driven from the end of the tube and that this action is some indication of the magnitude of the current interrupted.

This would indicate that in most cases, the fault current was probably of line-to-line or line-to-ground magnitude since such violent operation would not be attendant upon the progressive low-current failure of the winding for which the link was installed. From this one might conclude that the transformer faults initiated by lightning surge, mentioned in the report on field experience, are the principal cause of failure. There appears to be no other general cause of direct line-to-line or line-to-ground breakdown in the transformers. We would appreciate an explanation by the authors of what seems to be an inconsistency between the field experience and the supporting theoretical discussions in their paper.

E. A. Williams, Jr. (General Electric Company, Philadelphia, Pa.): The practice of placing fuses within transformer tanks has certain advantages over the use of external fuses as pointed out by the authors. To obtain these advantages, it is necessary to sacrifice some of the benefits obtainable with external fuses. Three outstanding sacrifices are:

1. The external fuse is easy to inspect and renew; the internal fuse necessitates dismantling the transformer.

2. The external fuse protects the system against bushing failures and flashovers; the internal fuse does not.

3. The external fuse does not create pressure within the transformer tank; the internal fuse does produce tank pressure.

The authors call attention to the force and power involved in an interruption by the protective link but omit data on tank pressure. What are the magnitudes of tank pressures?

J. K. Hodnette and M. G. Leonard: Some confusion evidently exists as to the distinction between an ordinary fuse and a protective link. We refer to a fuse as an integral device for circuit protection designed so that it can be readily replaced or reloaded after it has functioned to clear the circuit. A protective link is considered an integral part of a transformer designed to clear only faults which result from internal trouble, and therefore normally replaced only when the entire unit is to be repaired or replaced.

Most of the points raised in the discussion have been in regard to the comparative merits and performance of the two devices. These comparisons we are glad to make, particularly for applications in which the two devices have similar functions. Since the discussions overlap in many points, we will combine them all and deal with them in this form.

Co-ordination is one of the questions raised, both as to accuracy and width of band occupied. The band occupied by the protective link and the associated breaker is, of course, wider than would be occupied by a single device, but it is not wider than the comparable combination of a breaker with a fuse. So far as accuracy is concerned, the protective link is more accurate in performance than the fuse, because the fusible element of the link is of noncorrosive material; it is not subject to weathering; it is more uniform in size and resistance; it is many times stronger mechanically than commonly used fuse links. Moreover, it is protected against mechanical strain when used in small sizes, and finally its high melting point protects it from damage by momentary overcurrent.

Uniformity of characteristics, or accuracy, is only one of the requisites of current interrupting devices necessary for satisfactory co-ordination with other devices. The relative shapes of the current-time characteristics are of equal importance. The protective link offers a wide choice in shape, as shown in figure 3 in the paper, which makes it quite simple to fit it to the characteristics of either sectionalizing fuses or feeder breaker relays.

Charring of fiber tubes is suggested as a possible result of using a high-fusing temperature element. Actually, this does not occur, for two reasons: first, because the wire is not in contact with the fiber, and second, because the wire never reaches a high temperature in normal operation, i.e., in operation below the breaker trip characteristic. Operation above this curve occurs only on internal fault, hence for only a short time.

The rating of protective links on short-circuit test is in accordance with recommended AIEE practice. In regard to fusing time characteristic curves, catalogue data are available showing the performance of both the links and the associated breakers as used in distribution transformers.

The electrode travel required during operation has been questioned. The apparatus described in the paper was made to determine fundamental data on performance and was tested over an unusually large range of clearance in order to obtain as much information as possible from the test. Such a long travel is not necessarily required even in power transformers, and in distribution transformers only a relatively short travel is adequate.

The internal pressures produced by link operation have not been measured, for the reason that no difficulty has been experienced in this regard. It should be emphasized that one of the chief advantages of this new design over conventional construction is that its fast and effective quenching action causes a minimum of disturbance, with little burning of the electrodes and no serious pressure rise in the tank.

An Improved Polyphase Directional Relay

Discussion and author's closure of paper 41-62 by Bert V. Hoard, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 246–8.

Wm. R. Brownlee (Commonwealth and Southern Corporation, Jackson, Mich.): The application of the induction-loop principle to polyphase elements multiplies its usefulness. The use of a vertical shaft is a fortunate choice in producing a balanced element with more consistent operation than certain other types of relay elements. The advantages of the new device should be particularly great over the beam type of construction for use as a distance relay element. The inherent inefficiency of the beam has required very small and delicately adjusted air gaps (especially on the voltage element), which change in magnitude when the beam operates, thus depending on exact resetting against a fixed stop for accurate performance. In the writer's experience, minute particles of dirt (almost invisible on a cleaning paper) have resulted in calibration errors of over 30 per cent on beam elements of distance relays. In the new relay form, the air gaps are large and are not affected appreciably by the position of the moving element, and greatly improved operation is expected. The use of the new type element for distance relays should obviate the necessity of using a "negatively restrained" element (which is overbalanced in the tripping direction in the absence of both current and potential) and may permit the protection of moderately short transmission lines for which the beam-type relays had previously been considered inadequate. It is hoped that distance relays using this element may be available soon.

Standard or experimental applications of the induction-loop principle have been made by two prominent relay manufacturers, and both of them have standard applications of the induction-cylinder principle.[1,2] From a comparison of characteristics, it appears that the induction loop has a faster operating time, being on the order of one-third cycle minimum compared with about two-thirds cycle minimum for the corresponding induction-cylinder element. However, according to the author, it has not been possible to overcome the vibrating torque of the induction-loop element on unbalanced faults which is accomplished by the slight damping action of induction-cylinder elements. It would be interesting to know for what range of operation the action of the moving contact spring of the new relay is effective in following pulsations so as to maintain continuous contact.

The chief use mentioned by the author for the new relay is for directional-comparison type pilot-wire installations. Unquestionably the sensitivity at low voltages and currents, freedom from bouncing, etc., provide material advantages over the type CHV3 induction disk relay which was previously recommended for this purpose. However, the operating time appears to be too fast and it is doubtful if contact travel could be increased sufficiently without moving the loop too far away from the magnet poles. Pilot-wire schemes which provide complete coverage (including power supply from one end only) require a plunger relay to operate definitely ahead of the directional fault detector relay. Typical high-speed plunger relays part contacts in slightly less than one-fourth cycle, which is probably too close to the minimum operating time of the directional relay (about one-third cycle) for adequate margin. The pulsating torque characteristic on unbalanced faults is a serious disadvantage in pilot-wire application where it would not be at all serious in a distance element with local instantaneous seal-in auxiliaries.

It is also important that a directional relay with voltage restraint for pilot-wire service should cover adequately the extreme range of phase angles encountered in practice. For near-by faults, the phase angle of the line and fault impedance may approach zero degrees while faults near the distant terminal will be influenced principally by the transmission line which may have an impedance angle of perhaps 80 degrees. With standard watt elements it appears that the relay described by the author must cover an additional 30 degrees, depending upon whether the fault is between phases or involves all three phases. The difficulty of covering adequately a 110-degree range is all out of proportion to the extra 30 degrees, and it is suggested that the new relay be used with delta current-transformer connections, or that the equivalent of this be provided by winding each current coil in two sections, or that some other method[2] be provided to reduce the required phase-angle spread.

Values of sensitivity and operating time apparently apply to a single-element device with directional characteristics. What are the sensitivity and timing values with a two-element unit containing voltage restraint?

1. New Network Relays, J. M. Parsons and M. A. Bostwick, *Electrical Journal*, July 1937, page 288.

2. A Single Element Polyphase Directional Relay, A. J. McConnell, AIEE Transactions, volume 56, 1937 (January section), pages 77–80.

A. J. McConnell (General Electric Company, Philadelphia, Pa.): The author's statement that the trend toward high-speed relaying developed a need for a high-speed polyphase directional relay is quite true. In fact, this was recognized several years ago when the first induction-cylinder polyphase directional relay went into service.[1]

I cannot agree with the statement that the inductor-loop relay has all of the desirable characteristics inherent in the induction-disk type relay. Because of reciprocal action between the poles, the torque of the induction-disk relay (and of the induction-cylinder type) has no objectionable net double-frequency component, even when the relay is supplied with single-phase quantities. This is proved by figure 1 which shows two oscillograms of the instantaneous torque of a single-phase induction-cylinder directional relay. The lower film was taken at the maximum torque phase angle while the upper film was taken at only five degrees from the zero torque phase angle. Trace 1 in each instance is the instantaneous torque, trace 2 being the zero torque line.

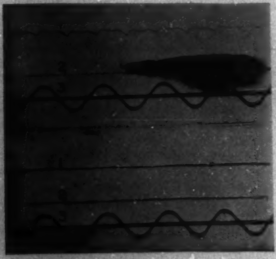

Figure 1

Of course, it is true that under balanced polyphase conditions, the relay described will have a steady net torque. However, during phase-to-phase faults, the pulsating torque may far outweigh any balanced torque which may be present, and tend to cause objectionable vibration. On the basis that the relay is capable of operating in one-fifth cycle (figure 6), one's first thought is that it could operate incorrectly if a pulsating torque were present having a negative loop, as may be the case with a phase-to-phase fault when the current is not at the maximum torque phase angle. However, it is doubtful that such high speed can be obtained in practice, since the time curves of figure 6 appear to be plotted to much higher input levels than would be encountered normally. For example, how would 50 amperes and rated voltage be obtained in an actual application? Furthermore, upon replotting the curves of figure 6, it is found that this relay is no faster than the corresponding induction-cylinder relay.

Although there may be no net pulsating torque under balanced polyphase conditions, there are certain to be pulsating translational forces because of continuous change in the point of application of the force. For example, as drawn in figure 1, the lower magnet will apply, at some instant, its maximum force to the left (assuming clockwise net torque). At some other instant, the upper left-hand magnet will apply its maximum force upward and to the right, and at still another instant, the upper right-hand magnet will apply its maximum force downward and to the right. Thus, there might be continuous sliding of the bearing pin on the bearing, and if so, it would appear that excessive bearing wear might eventually ensue.

With single-phase relays of the loop type it was the practice, at one time, to reduce vibration by means of early saturation of an auxiliary current transformer, with a consequent drastic reduction of torque. Does the relatively small cross section of the current iron (figure 1) signify that the same result is obtained by early saturation of the magnetic circuit of the current coil? What is the torque developed by this relay at rated voltage and current, and at the maximum torque phase angle?

The phase-angle curve at two volts shown in figure 5 is very good. Can all production relays be expected to have a similar characteristic? Ordinarily, current bias torque is caused by manufacturing variations. The relay described appears to have an additional factor affecting current bias, namely, position of each loop relative to its current pole. Is the adjustment of the position of the loops in the air gaps the method of eliminating current bias? If so, is it not necessary to readjust for the elimination of current bias if the contact adjustment is disturbed? If the necessity for this readjustment were not realized, a change in contact setting might cause incorrect directional action at low voltage. Also, if the current bias is dependent upon loop position, will not the low-voltage phase-angle characteristic be different, depending upon which contact is closed when the fault is applied?

Regarding the voltage restraining element of the relay illustrated in figure 7, a nonpulsating net torque with balanced voltages is obtained by using all three combinations of delta voltages. However, during an unbalanced fault, a pulsating net torque appears. In the case when one delta voltage becomes zero, there may be zero average torque, but the magnet supplied with the uncollapsed voltages will have a pulsating torque of considerable magnitude.

Reference

1. A Single-Element Polyphase Directional Relay, A. J. McConnell. AIEE Transactions, volume 56, 1937 (January section), pages 77–80.

Bert V. Hoard: With reference to the oscillograms on torque submitted by Mr. McConnell, it would be of interest for him to describe the method of obtaining them. It is well known that any single-phase source of power produces vibrating torques similar to those shown in the paper, the vibration being largest near the phase angle of zero torque. If these oscillograms indicate the vibration of the induction cylinder after the single-phase torque pulsations have been smoothed out by the relatively high inertia of the moving element, we agree with him, but we doubt very much if the actual torques produced on the moving element by single-phase power are as shown. A similar smoothing effect, but to a lesser extent, is produced by the inertia of the inductor-loop moving element.

We realize it will be an exceptional case if a directional relay has to operate on a three-phase fault of 100 amperes and sustained voltage, which indicates an infinite bus at the relay location. However, if such an operation is possible on a certain system, there is a probability of an unbalanced line-to-line fault occurring at the same fault location, in which case the maximum power supplied to the relay would be half or less than half of the three-phase power which would be supplied during the three-phase fault. Thus, during the unbalanced fault, while pulsating torques are present, the total torque magnitude is materially less than when the equivalent three-phase fault occurs, so that the smoothing out effect of the relay inertia is greater relatively than would be expected. Also, the time to close contacts is correspondingly increased. For these reasons, the possibility of reverse operation due to a negative loop of torque on one phase of the relay has been taken care of in the design. The 90-degree connection gives a torque on the relay equal to the arithmetical sum of the positive and negative sequence components of power. The 60-degree and 30-degree connections give vector summations of these two components of power at 60 degrees and 120 degrees, respectively. Hence, the 90-degree connection gives a greater torque for a line-to-line fault than the other two connections, and, therefore, the timing obtained is nearer to the timing obtained for the three-phase fault.

We agree with the theory that there are pulsating translational forces which in combination with the moving element stop may produce sliding of the bearing pin on the bearing. There is no relay made which utilizes either the principle of the rotating field or the principle of the inductor loop that in theory may not have such sliding within the bearing. Practically, however, there are many relays in which such sliding is negligible and this relay is among this group.

The narrow iron section used for the center leg of the electromagnet fulfills three objectives.

1. For high values of current it saturates, and in this manner prevents any unnecessary increase in relay torque. Thus, the torque increases only by a ratio of 7 to 1 while the current is increasing by a ratio of 20 to 1. At 5 amperes and rated voltage the torque is approximately 30 centimeter grams. The wide air gap allows considerable flux fringing, hence the saturation in the center leg takes place slowly and progressively with increase in current above 30 amperes, and there are no sudden bends in the phase-angle curves.

2. The narrow thickness in the center leg gives a very small amount of current centering torque, so small in fact that at 100 amperes less than 1 volt will operate the relay.

3. The narrow iron section combined with the shape of the section threading the loop provides a small amount of voltage decentering torque. This torque is present on one side of the neutral point and by a simple contact adjustment can be made to act as a small amount of voltage restraint. This restraint, of course, completely disappears at low voltage. The relay is normally adjusted so that the decentering torque will always return the tripping contact to the open position when no current is flowing and this adjustment also automatically locates the loops in the proper position to minimize the effects of the current centering torque. This simple contact adjustment with voltage alone applied can easily be made in the field.

With regard to the voltage restraint element, during a phase-to-phase fault in which one voltage is zero, the torque of two units is reduced to zero because the collapsed voltage is applied to one circuit of each unit; the torque of the remaining unit has 86 per cent of normal voltage applied to each circuit or 75 per cent torque for the unit, but at the phase angle of zero torque for the unit. Thus, the pulsation cannot be greater than one-third times 75 per cent of normal restraint or the equivalent of 2.5 amperes, since normal restraint is 10 amperes. This small value is not objectionable.

The contacts of the relay are effective in following pulsations so as to maintain continuous contact during high-current unbalanced faults except for a range of five degrees away from the zero torque characteristic. For balanced faults this range is approximately two degrees.

We can see no material advantage of the 60-degree connection or its equivalent plus a phase shifter, over the 90-degree connection with a phase shifter both to obtain substantially a 45-degree maximum torque characteristic for three-phase faults. Practically equal performance of the two connections is obtained for unbalanced faults as well as for balanced faults. Mr. Brownlee's reference to standard watt elements and 110-degree range is not clear, unless he feels that the phasing loops used on the current circuit to obtain the 45-degree characteristic are perhaps more complicated than the relay without phasing loops but with additional current transformers to obtain the 60-degree connection.

Values of sensitivity and operating time of the double-element relay which has voltage restraint are available in the standard catalogue section published by the manufacturer.

Modern Relaying for A-C Secondary Network Systems

Discussion and author's closure of paper 41-81 by D. L. Beeman, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 237–41.

R. D. Wilder (Public Service Electric and Gas Company, Newark, N. J.): This single-element network relay is particularly advantageous where secondary networks are supplied by wye-connected transformers such as the 4,150-volt, three-phase, four-wire system utilized by Public Service Electric and Gas Company for their network supply. It is too bad that Messrs. Beeman and McConnell did not have this inspiration a number of years ago, as we have had numerous locations where the *L-N* type relay would not receive its necessary quota of watts on some types of faults.

However, the older types of relay can be improved considerably by a few simple tricks that may not be generally known. If the potential coil-neutral ground connection is opened, the relay neutral will float to a more advantageous point on single and two-line-to-ground faults. Referring to table I in this paper, the per cent of normal torque may be increased from 1.7 to 6.9 per cent for 10 per cent volts, from 11 to 21.5 per cent for 25 per cent volts, and from 81 to 92 per cent for the 70 per cent voltage fault. The double line-to-ground fault, table II shows a corresponding increase from 4.2 to 5.1 per cent. Line-to-line faults are not affected.

Relay operating time is an important item where fault currents are large and selectivity with substation breakers must be considered. The new relay described in this paper shows a notable improvement in operating time. Here too, the older network relays can be improved. Most of these are provided with various leaf springs for obtaining the required reverse-current settings. By using the stiffest spring practicable for getting the desired setting, the relay operating time may be reduced by 40 to 50 per cent. This is presumably due to the greater proportion of free contact travel before the stop hits the restraining spring.

The new relay described by Mr. Beeman does have the improved characteristics which are particularly suited to the smaller capacity medium-voltage networks such as the Public Service has been constructing recently in New Jersey.

D. L. Beeman: Mr. Wilder's suggestion of disconnecting the potential coil neutral, from ground, of conventional network relays with line-to-neutral connected potential coils increases the relay torque for ground faults only. The increase in torque, however, is about one-half as great as if line-to-line connected potential coils are used. Disconnecting the potential coil neutral from ground of line-to-ground connected potential coil relays is of no benefit for unbalanced faults not involving ground. Consequently, it is of no benefit on systems using network transformers with delta-connected high-voltage windings.

Lead Storage Batteries in the Transportation Field

Discussion of paper 41-34 by Roland Whitehurst, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 303–07.

W. S. H. Hamilton (New York Central System, New York, N. Y.): Once in a while it pays us to pause for a moment to take stock of our progress in a given field, see what our wants are at present, and try to picture our requirements for the future. Mr. Whitehurst has covered the first two items well in his paper and some of the rest of us should state what we think the future ought to bring, even if we ourselves are unable to indicate how those results can be accomplished.

Before commenting on the possibilities of the future, there is one point to which I wish to take exception in Mr. Whitehurst's paper. Under section *B*1 he gives the intimation that when the railroads did away with the Planté batteries, they adopted a single-life battery, the intimation being that at the end of the useful life of the elements the entire battery was scrapped. Such has not been the practice on our system and I know it is not on a number of other railroads. We have, ever since the introduction of the pasted-plate batteries, made a practice of renewing elements in existing jars and trays in the case of the wooden-tray batteries and this practice is more desirable than ever in connection with the rubber Monobloc containers. We have in service some jars that are approximately 25 years old and while the life of wood trays of course is nowhere near this long, there is no reason why under reasonably good conditions the life of two sets of elements cannot be secured from even wood trays. Therefore, we do not agree with the policy of discouraging the rebuilding of batteries in the railroad company's shops, and have secured very successful results in recent years from the purchase of wet-charged elements which require the minimum of working to place them in condition for use.

Table III gives a very good idea of the progress which has been made over the years since 1920 in reducing space and weight for the same rating of battery. In between the 1920 and 1940 figures, there could be inserted the figures for a typical pasted-plate battery of 1930 which had a weight of about 1,850 pounds.

While this very great improvement in weight and space has been made possible primarily by two rather radical improvements, namely the substitution of the pasted plate for the Planté, and the rubber Monobloc container for the wood tray with jars, there have also been a great many other gradual improvements over the years which have materially helped in accomplishing the over-all result.

As far as the future is concerned there is still the opportunity for someone to make a radical discovery or improvement in batteries that would change the whole picture completely. Such a battery might even be based on a new concept of storing energy and the change from those of our present knowledge would have to be as distinct in concept as the difference between the reciprocating steam engine and the gas turbine.

The researches in plastic materials indicated by Mr. Whitehurst will be most helpful if a reasonably transparent container results, which will enable inspections to be made without removing the elements, or probing for sediment as is now necessary. As an alternate arrangement there is the possibility of providing a transparent window only in the container.

Looking now toward specific applications in the future, in the Diesel locomotive field there is need for standardization of the number of cells in batteries much the same as has been accomplished on passenger cars by the adoption of 16- and 32-cell batteries. This work has already been undertaken by a committee of the AAR. There are many reasons why 32 cells is a good choice for the larger sizes of locomotives and should conditions ever require it, there is the possibility of series paralleling two groups of 32 cells each for cranking purposes in the manner as described by Mr. Whitehurst for 12/24 volts for cranking Diesel engines in busses.

In the car lighting and air-conditioning field there will undoubtedly be an extension of the use of internal combustion engines on passenger equipment cars in the future and the advent of the d-c fluorescent lamp will probably swing the trend toward the use of the 64-volt system with 32-cell batteries. Incidentally this lamp can be operated on both alternating current and direct current by selecting the proper a-c voltage which adds to its versatility.

For cars with electromechanical air conditioning there should be a decided trend toward providing means on the cars themselves for converting from 220-volt, three-phase, 60-cycle alternating current to direct current for charging the battery. Only those who have been intimately connected with the problem of providing d-c yard battery charging facilities realize the cost and complications involved. The general provision of 220-volt, three-phase, 60-cycle a-c power for stand-by operation of air-conditioning equipment on cars has made available a much less expensive, more efficient, and more readily handled source of power for this purpose. Several means are available for converting this power to direct current: rectifiers, genemotors, and a-c–d-c compressor motors being the ones commonly used, with the genemotor apparently offering the greatest advantages at the present time.

While it may sound fantastic today, I believe that a battery which can be charged directly from alternating current is not beyond the realms of possibility within the next 20 years. Reference was made to this in Mr. Noertker's paper on "Unsolved Problems of Electrical Engineering in the Field of Transportation" (AIEE TRANSACTIONS, volume 59, 1940, pages 992–6) presented at our last winter convention.

Incidentally I have always been a firm advocate of the 64-volt system with 32 cell batteries for electromechanical air-conditioned cars and the New York Central system has 367 of such cars now in service, all with 600 ampere-hour batteries. The individual trays are lighter and more easily handled, the cables, generator, and motor commutators are smaller and one does not have to be continually on the lookout for the least voltage drop at every point in the circuit as with the 32 volt system.

The New York Central system was the first railroad to adopt the wrapped Monobloc container for air-conditioning batteries and we now have approximately 320 such 32-cell batteries in service using 5,120 containers.

In connection with air-conditioning batteries there is need for further investigation of the relative capacities at high and low rates of discharge, especially as the batteries become older. We are much interested in the three-hour rate at the present time and are basing the transfer from heavy duty (electromechanical) cars to light duty (mechanical) cars on tests made at approximately this rate.

We find in these tests that sometimes batteries will more readily meet the high-rate test than they will the low-rate test, and that different makes of batteries act differently in this respect. Further study along these lines is indicated.

In closing I hope I will be here in 1961 and hear what progress has been made in the next 20 years in storage batteries and also see how closely the developments have followed such predictions as are here given.

Complete Analysis of Motor Temperature Rise

Discussion and author's closure of paper 41-29 by Fremont Felix and H. G. Jungk, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 578–86.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This paper is especially interesting to me because it brings out so clearly the different temperature limitations of electric motors. Most electrical apparatus, however, has other limitations besides thermal ones, and I should like the authors to say what these are and what their relations are to the thermal limits for the railway motor case. I suppose that the slipping point of the wheels establishes a limiting torque for each speed, and that the commutation limit is set by design to be somewhat above this torque limit at all points. It will be helpful if these torque and commutation limits could be indicated on the performance curves.

H. G. Jungk: As Mr. Alger states generally about electrical apparatus, all a-c, single-phase commutator railway motors have definite limits in design and service. The slipping point of the wheels defines the number of poles, field strength, and armature ampere turns required. The maximum current density of the brush contact surface and volts between adjacent bars determines the size and number of brushes and commutator bars.

Maximum accelerating tractive effort per axle and speed to which this maximum accelerating tractive effort is maintained defines the copper size for maximum accelerating currents and the commutation requirements. The range from this speed, to which maximum tractive effort is maintained, up to maximum sustained service speed determines commutation requirements and transformer capacity to supply the power. The maximum sustained speed is limited by the mechanical design of the armature and commutator, gear ratio, and wheel size.

These relations then give the "envelope" or curve from zero to maximum service speed showing all the limits of operation. Then time-temperature curves within this envelope define all the limits due to temperature rise.

The time-temperature curves, as appear in our paper, are limited by such an envelope. The maximum starting and accelerating tractive efforts are limited at the maximum setting of overload switches, the range from accelerating tractive effort to maximum sustained service speed is limited by the highest voltage speed curve available on the locomotive, and the maximum speed is the maximum sustained service speed.

Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause

Discussion and author's closure of paper 41-45 by G. A. Matthews, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 596–604.

J. A. Elzi (The Commonwealth and Southern Corporation, Jackson, Mich.): The comprehensive series of tests made in connection with this investigation are not only indicative of the fact that the equipment developed is effective in protecting covered wire from burndown and avoiding the blowing of fuses on transient faults, but also provides very valuable factual data regarding the behavior of arcs under various conditions. While the author stresses the above two features of this equipment, it appears that the devices which have been developed, particularly the reclosing breaker, possess other desirable features thus providing a welcome addition to available circuit interrupting devices.

Since the reclosing breaker must be selective with fuses or relays after the initial instantaneous operation, it would be interesting to have a little more information regarding the time delay tripping device and whether or not it can be set to be selective with relays and fuses.

The two-cycle switching speed of the

reclosing breaker no doubt produces voltage surges considerably higher than have been experienced on distribution circuits in the past with conventional circuit breakers. This may introduce additional problems, and it would be interesting to know if the author has had occasion to obtain any data on this point.

E. V. Sayles (The Commonwealth and Southern Corporation, Jackson, Mich.): The thoroughgoing analysis by Mr. Matthews of the behavior of transient faults on overhead distribution lines and the results of his work leading to the development of high-speed switching devices are a valuable contribution to the industry in its effort to improve service.

One of the most valuable results of these studies is the development of the short-circuiting device designed to prevent the burndown of even the smallest sizes of weatherproof conductors commonly used for overhead distribution systems. Because of this device, transient faults can be automatically cleared so quickly that branch fuses protecting the circuit will not operate.

It is interesting to consider the use of the fast reclosing breaker as a low tension switching device at small distribution substations where the step-down transformer capacity does not exceed 2,500 to 3,000 kva. The simplicity of the reclosing breaker makes possible its mounting directly on brackets attached to the tank of transformers or regulators, and should simplify distribution substation design where the requirements of the distribution system permit the use of unit type equipment. Substantial savings, subject only to the limitation in capacity of the new device, should result from its substitution for conventional equipment. While the tests described were all made on a 4,800-volt ungrounded system, it is reasonable to assume that the advantages of this new equipment could be realized on the conventional multi-grounded four-wire distribution system as well.

To one who has witnessed many of the tests of this equipment, the greatest single feature of the fast reclosing breaker is the high speed of circuit opening and closing on the initial operation. This over-all time of six cycles is so short that the customer's reaction to the loss of voltage for this duration can be placed in the "insensible zone."

The possibilities of improved distribution system design which these devices offer should serve to stimulate the interest of distribution engineers. Although field experience may lead to improvements of the devices, the fundamental principles on which they are based and the protective scheme which they embody are essentially sound.

A. H. Kidder (Philadelphia Electric Company, Philadelphia, Pa.): Mr. Matthews is to be commended especially for his development of the fast-opening circuit breaker for distribution circuit protection. It should prove to be extremely useful for preventing unnecessary distribution branch-line fuse operations. The breaker is small and well adapted to pole-top installation. It has a load rating and interrupting capacity that is adequate for almost any distribution circuit. It will open quickly enough to protect suitable fuses against operation before nature has been given some opportunity to clear the circuit of the trouble. Distribution branch-line fault sectionalizing is almost indispensable with bare wire construction. Each branch-line fuse operation prevented, however, saves about one hour of outage for the customers on the branch. This, I think, is a very fine opportunity for the Matthews' breaker.

I am not by any means disinterested in the problem of burndown. My own experience indicates that well over 90 per cent of all line faults in four-kilovolt construction is due to other causes than power arcs following lightning flashovers. Mr. Matthews' motion pictures left no doubt that the covered wires will burn down, if a tree limb or other similar construction holds the wires close enough together so that the arc will restrike when the Matthews' breaker recloses. Covered wire burnoffs, figure 2 in the paper, and fuse operations are very nearly alike in their current time characteristics, however, so that a system which will prevent significant wire injury before the first opening of the breaker, can also be used to prevent fuse operation before the first opening of the breaker.

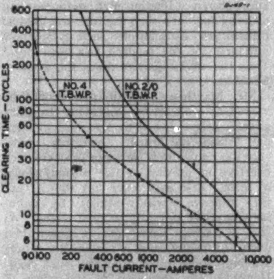

Figure 1. Total self-clearing time for 2,500-volt faults between covered wires

The interval between the initial opening of the breaker and its first reclosure deserves more consideration than has been given to it, I think, because the wires will burn down or the fuses will blow unnecessarily, if the breaker recloses prematurely. My own experience suggests that the lightning flashover of line insulators is almost innocuous at four kilovolts. I attribute this to the likelihood that power arcs will not be ignited by a lightning flashover path whose length is greater than five inches per kilovolt[1] of the operating potential between conductors. The tree branches which cause the preponderance of our distribution circuit troubles may move slowly enough to make a 5- to 15-second delay desirable before undertaking the first reclosure of the circuit breaker. I understand that the Matthews breaker can introduce some such interval, if it should be found to be a sufficiently important factor. For the present, however, it seems quite probable that fast reclosing, such as is characteristic of repeater fuse installations, may not be nearly so effective at four to five kilovolts as it is at the higher voltages.

Mr. Matthews' figure 2 gives only the time required to sever the conductors. For those who may be interested, I am including a figure which shows for two wire sizes of covered wire, the total fault clearing time required to sever the conductor and to extinguish the accompanying power arc at 2,500 volts. Our tests of total fault clearing time were made with slack wires, about four years ago, in an attempt to appraise the maximum probable severity of covered wire faults.

1. LIGHTNING PROTECTION OF MEDIUM-VOLTAGE LINES, H. N. Ekvall. AIEE TRANSACTIONS, volume 60, 1941 (March section), page 130, figure 2.

D. K. Blake (General Electric Company, Schenectady, N. Y.): One is impressed with the thoroughness and the magnitude of Mr. Matthews' investigation. His data on the burndown characteristics of wire and determination of amount of burning permitted without serious reduction of mechanical strength ought to be very useful to the industry.

Service outage data from other companies, as well as his own, point to the primary system as the place to spend money to realize a substantial reduction in outages to the consumer.

G. F. Lincks (General Electric Company, Pittsfield, Mass.): Mr. Matthews has made a noteworthy contribution to the study and improvement of overcurrent protection on distribution systems not only in providing operating statistics, test data, and new equipment but in helping us think more clearly on this vital subject. Distribution primary lines in general present the greatest exposure, the greatest potential hazard due to location on the city streets and along the traveled way, and by actual record, cause the greatest percentage of consumer minutes outage. Line sectionalizing and branch-line fusing have proved a very effective remedy, employed by an increasing number of utilities across the country during the past few years. Wherever Mr. Matthews' new developments can be included they should prove complimentary to this whole program affording the increased advantages he describes.

It would appear that the data in table I could be of greater value if we could know what percentage of the number of wires burned down in 1938 and in 1939 were of the total outages in the respective years. In other words, is this problem 10 per cent or 90 per cent of the total overcurrent protection problem?

Studies on a large number of systems have shown that a high percentage of them have very largely outgrown the protective orbit of the station breaker and its overcurrent protective relay. Unless some additional protective device, such as a sectionalizing fuse, is provided for this outlaying area, faults must either burn clear or burn the line down with the attendant hazard to life and property. If Mr. Matthews could break down the data in table I to show the percentage within and without the protective orbit of the station breaker and with or without fuse or other protection, it would be helpful in determining the relative values to be derived from protection and by the various methods available. Additional test data would be valuable as to the annealing effect on hard drawn wires from the heating of sustained fault currents which would cause sagging and thus a greater tendency for lines to swing together and cause more faults.

There is one cautionary note that should be sounded. In these days of increased use of automatic open and reclosing and now short-circuiting equipments we should not overlook the fact that practically every consumer is advised of every interruption in voltage supply, no matter how short it may be. The telltale on the electric clock flashes red. The consumer has no way of telling whether the outage was for a fraction of a cycle or for several minutes except by checking some mechanical clock or an outside source. If momentary outages become too frequent, service may be impaired psychologically even in cases when actually it is being improved. The results can show up adversely in the commercial sales from which all our revenue is derived. Every scheme requesting *only a momentary dip in voltage* should be weighed carefully in this respect. Mr. Matthews' methods probably will find a justifiably wide usage whereas other schemes will and should be discarded.

There are two probable reactions to Mr. Matthews' discussion of the problem as it affects future trends in distribution fuse link design. One is to provide a line of slow fuse links having time-current characteristics that line up with those suggested in figure 15 of the paper. The names or ratings may differ somewhat. The other is to make a line of fuse links fast enough to provide equal protection to that of the shorting contactors, even though they do cause a permanent outage to a few consumers and demand manual replacement after each outage.

The requirements for slow fuse links for use with the shorting contactors is reasonably within the possibility of practical design. In fact, a comparison shows a close similarity of these requirements with those for co-ordination with the small low-voltage service entrance breakers[1] for which fuse links are now available. The actual difference between existing fast and these slow links is slight. For example, there is a trend to standardize[2] on a one-tenth second melting current range for fast links, of 10 to 20 times the rating (5 to 10 times the 300-second melting current for any basis of rating). These values are inclusive of the plus 20 per cent allowable variations.[2] A line of the desired slow links would fall within a range including variations of from 17 to 25 times the rating ($8^1/_2$ to $12^1/_2$ times the 300-second melting current). The overlapping of the fast and slow ranges includes only the allowable plus 20 per cent variation of the fast fuse links. To avoid this an over-all range for all fuse links might be made from 10 to 25 times the rating (5 to $12^1/_2$ times the 300-second melting current) with a dividing line at 17 times the rating ($8^1/_2$ times the 300-second melting current). Then fuse links with melting time-current characteristics including variations which fall to the left of this dividing line will meet the requirements of fast links for the best co-ordination with relays. Those falling in the range from 17 to 25 times the rating including variations will meet the requirements of slow links for co-ordination with the shorting contactors and with low-voltage service entrance breakers.

According to the curves figure 3 of the paper, it is not practical to make all ratings of fast fuse links protect all wire sizes from number 6 to 1/0. However, a more careful study of the data for the curves in figure 2 of the paper will probably show that the majority of fuse links normally called upon to protect number 6 conductors in service will provide ample protection and a similar condition will exist with other fuse links and conductor sizes. Doubtless there will be cases where such protection is not possible and this should be taken into consideration. Making fuse links melt faster, while a practical design job, would adversely affect the co-ordination with motor starting demand currents when the fuses are used at transformer installations such as are now provided by the modern fast fuse link.[1] Thus the advisability of doing this is questionable.

Mr. Matthews' contribution should be viewed as a means for improving the gains already accomplished by line sectionalizing and branch-line fusing. Operating experience has shown that such practices are very effective in preventing the burning down of lines. Also experience has shown that they improve service continuity by confining the effect of faults to small areas. As Mr. Matthews points out, a blown fuse makes all faults cause a permanent outage although some might otherwise burn clear. However, the reduction of the effect of permanent outages which otherwise would take out the whole line tends to more than offset the increases in consumer minutes outage from the permanent interruptions to a few customers which otherwise would have cleared without an outage. Mr. Matthews' shunting contactors working in close co-ordination with fuse links make possible a further reduction in consumer minutes outage and the elimination of more of the hazards attendant upon the burning down of lines.

H. L. Wallau (Cleveland Electric Illuminating Company, Cleveland, Ohio): Distribution engineers should welcome Mr. Matthews' contribution to their art. The data assembled are extremely interesting and valuable. The author states that the percentages of transient to total faults have been variously estimated at from 50 to 90 per cent; he sets the Detroit ratio as of 60 to 70 per cent. I believe his estimate is conservative. Statistics for 1938 and 1939 for five systems with which I am familiar indicate a ratio of 80 per cent for that period. It is probable that some of the nonself-clearing faults included in the 20 per cent of total faults were initially transient (self-clearing) faults and would not have developed into permanent faults if the voltage had been collapsed in a time of the order of $^1/_2$ cycle.

But whether 50 per cent or 90 per cent, if the transient faults developing on a system can be snuffed out before material damage is done to distribution facilities and with scarcely perceptible service interruption, a tangible economic and an intangible psychological gain have been achieved. The net economic gain is the less the greater the cost of the installed facilities required to accomplish the desired results.

The author modestly attributes the development of the devices described to the Detroit Edison Company. I trust you can all read between the lines. He deserves credit for having studied the mechanism of flashover between conductors, for having made quantitative determinations of the effect of arcs of various magnitudes and durations upon them. With these data he developed the simple self-contained and self-operating devices necessary to furnish the requisite protection against conductor burndown, which devices he indicates are sufficiently low in installed cost to justify their use in many localities.

Some of us who have been fortunate enough to see moving pictures of a number of the author's tests can testify as to the effectiveness of the devices.

H. P. St. Clair (American Gas and Electric Service Corporation, New York, N. Y.): It seems to be quite a unanimous verdict, in which I wish also to concur, that the industry is indebted to Mr. Matthews for valuable data on arcing and burning characteristics of distribution lines under fault conditions and for the development of very effective and, we take it, not too expensive equipment for rapidly getting rid of the arcing for transient faults and quickly restoring the lines to service.

It might be of interest to speculate on the extent to which the problem has been affected by the nature of the system involved, that is, the isolated delta 4,800-volt, three-wire system. Certainly, the hazards to the public and to maintenance personnel are affected by the inherent possibilities of having lines on the ground without the flow of fault current for prompt relay action, although this would not apply to conductors placed on the ground as a result of phase-to-phase arcing. Neither does a fallen conductor upon a grounded system of this voltage class insure sufficient fault current for relay action as has been demonstrated many times.

I should also like to ask how much the actual fault current is increased when a phase-to-phase arc is replaced by a dead short circuit by the short-circuiting contactor. In other words, while the contactor kills the arc and prevents the burning of the wire, does it also serve any purpose in providing greater fault current for positive relay action?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Several years ago a number of large utilities exchanged operating records for a few years for distribution systems operating at about four kilovolts. Studies in Chicago in connection with this activity have shown that the average customer has an interruption about once every $2^{1}/_{2}$ years and that the prolonged outages, such as occur incidental to conductor burndowns, occur about once every $4^{1}/_{2}$ years. This seems to be excellent service and results in a brake on any enthusiasm that may develop for additional expenditures to use the ingenious equipment developed by Mr. Matthews. Troubles on primary wires in Chicago are cleared by the functioning of relays and breakers at the substation.

In the Chicago system, which is essentially urban in character, there were 345 cases of trouble involving primary wires burned down in the years 1938 and 1939 as compared with 1,696 on the Detroit system according to table I of the article. The Chicago system had about 1,500 circuit miles of four-kilovolt, four-wire, grounded-neutral overhead primaries, which I suspect was somewhat less than on the Detroit system, which included territory outside of the city of Detroit. It would be of interest to know the approximate number of troubles and miles of circuit for the city of Detroit only.

P. A. Jeanne (Bell Telephone Laboratories, Inc., New York, N. Y.): Mr. Matthews' paper gives, among other things, information which is of special interest in the consideration of joint use of poles by power distribution feeders and telephone facilities. It has been previously determined that in the order of 60 per cent of all contacts between power conductors and telephone plant in the voltage range from 5 to 15 kv are due to power supply conductor failure. Thus, any device or improvement in operating methods which will reduce the probability of conductor burndown is beneficial to joint use.

While the author confines his description largely to the clearing of phase-to-phase faults, it is presumed that the devices he describes could be made equally applicable to phase-to-ground faults on a grounded-neutral system. Perhaps the author would like to comment on this phase of the matter.

The joint subcommittee on development and research, Edison Electric Institute and Bell Telephone System, have recently completed an extensive oscillographic study on a number of grounded-neutral power distribution feeders principally to determine the operating performance of feeders equipped with various protective devices and schemes. The observations were conducted largely on circuits provided with ground relaying. In some instances the feeders were also equipped with repeater-type fuses and pole-top oil-circuit reclosers. The study covered periods from 4 to 55 months of observation on 20 selected distribution feeders having a total mileage of approximately 1,000 miles and operating at voltages ranging from 4 to 13.8 kv. Records from approximately 4,000 accidental disturbances were obtained and as far as possible each disturbance was correlated with the trouble on the feeder.

A few of the pertinent data obtained are listed below:

1. RELIABILITY

It was found that relays, fuses, and circuit interrupters operated consistently and reliably on currents at or above which they were set or designed to operate.

2. CAUSES OF FAULTS

Approximately 70 per cent of all faults involving ground were attributed to lightning and approximately 90 per cent of all faults caused no reported damage and may be classified as transient. Faults, as used in this classification, include disturbances having durations in excess of about one cycle.

3. BURNED-DOWN OR BROKEN WIRES

The percentage of total faults involving wire failures ranged from about 0.5 to 46 for the various feeders. Their frequency of occurrence ranged from about 1 to 23 per year per 100 miles of line. Lightning was responsible for about 19 per cent of the wire failures, the remainder being associated with objects getting into or hitting the line.

4. SPEED OF FAULT CLEARANCE AND RECLOSURE

On feeders equipped with instantaneous relays and for immediate automatic reclosures, average time from initiation of fault to first breaker opening ranged from 7 to 15 cycles for the various feeders; average time from initiation of fault to first reclosure ranged from 34 to 57 cycles.

5. MANNER OF FAULT CLEARANCE

The number of faults which were cleared by circuit breaker operation ranged from a very few on extensively fused systems to 76 per cent on systems with limited fusing. On systems equipped with instantaneous relaying and rapid reclosure, considering only those cases in which the fault current persisted until the breaker first opened, the feeder was clear of fault upon first breaker reclosure in from 50 to 100 per cent of the cases for the various feeders, the average for all feeders being approximately 75 per cent.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Matthews reviews an intensive investigation of means for improving radial distribution line service. He is correct in saying that commercial apparatus does not give the speeds he finds desirable. The fastest small indoor conventional circuit breaker equipment operated with reclosing relays set for instantaneous first reclosure gives approximately 20 cycles from moment of short circuit until contacts retouch. While this performance seems generally satisfactory, we must doubt its complete adequacy in view of the data presented by Mr. Matthews.

This paper gives a review of service requirements and, in addition, describes three devices:

1. A high-speed reclosing circuit breaker
2. A shorting contactor
3. A shorting contactor with circuit-opening devices.

Each of these units is self-contained and operated by series high-tension auxiliaries.

Because of general interest in this subject, which is being worked on by several groups, a clear understanding of industry requirements at this time is highly desirable.

Over 20 years ago high-speed reclosing was used on feeders that gave three complete operations in a total elapsed time of 1.5 seconds. Also, on the same system at about that time arc suppressors were used on 26-kv lines to short-circuit flashover. However, the general use of reclosing equipment has in later years made the arc suppressor for that voltage obsolete.

Again, great improvements have been made in reclosing equipment especially for high-voltage service. High-speed breakers in themselves have reduced the time necessary to deionize the original fault and have made fast reclosing speed usable. Thus, we have 138-kv apparatus on major transmission lines giving over-all reclosing speed of 18 to 20 cycles.

Comparable improvements can be made in low-voltage equipment if sufficient demand exists. Mr. Matthews' paper strongly indicates that such a demand may be growing. The type of device to service such a demand should be carefully considered. The type described in this paper doubtless has a field; however, the general results of reclosing service reported by the EEI shows that over 80 per cent of all overhead line faults are satisfactorily cleared on a first reclosure and thus present standard equipment is doing reasonably well. If required, considerable improvement can be made along present conventional lines by the use of high-speed interrupters, fast reclosing mechanisms, and proper relays.

I suggest a symposium on this subject, possibly at the summer convention, at which the operators could state their requirements for the future and the interested manufacturers indicate their ability to service such requirements.

Mr. Matthews' paper gives so concretely the advantages to be gained step by step with increased service restoration speed, that a reaffirmation of existing standards or a realignment of ideas on this important subject is required.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): I was particularly interested in the work of Mr. Matthews and his associates as described in his paper on arc-over on overhead distribution lines from the standpoint of reducing to a minimum the arcing time of a circuit in order to reduce effect on service and damage to the distribution conductors. This is carrying out on a distribution system the same kind of work that we have carried out for the last five years on our high-voltage transmission circuits by the use of our ultrahigh-speed reclosing equipment. The order of time developed by Mr. Matthews of possibly one-half to two or three cycles is given as the maximum fault time now conceded to be that within which damage can be kept to a negligible figure. It is interesting to recall that when the first lightning committee of the AIEE was formed in 1926 that the writer, who was then secretary of the committee, consisting at that time of Messrs. H. H. Dewey, C. L. Fortescue, and M. L. Sindeband, was present at its first meeting, and heard the committee's agreement to the effect that provided relay time on a high-voltage circuit could be kept to a maximum of three to four seconds, no concern need be felt for trouble with conductor burning.

We of course know today that that time has been cut to the order of three or four cycles instead of seconds for high-voltage lines, and Mr. Matthews' work shows that the same order of time is necessary in a distribution system.

Mr. Matthews and his associates are to be complimented upon the equipment that they have helped to develop to effectuate these results. I think, however, it might be pointed out here that other means for accomplishing the same result undoubtedly can and will be developed as times goes on. That, however, is not intended to detract in any manner from the credit that Mr. Matthews and his associates deserve.

G. A. Matthews: The author appreciates the wide interest shown in the paper. Many of the discussions submitted require no comments but the nature of some leads to the belief that there may be confusion with respect to the primary aim that lay behind the research and development reported. This belief is based upon references to operating performances and to statistical data intended, no doubt, to be pertinent to the problem but which, in reality, are not correct measures of the facts with which the project is chiefly concerned.

To clarify this apparent confusion the author wishes first to emphasize that the primary object of this work was not to improve quality of service but to decrease hazards associated with distribution wire burndowns. The word, decrease, is used advisedly, for it was not the intention to eliminate all burndowns. As pointed out in the paper, the expedient of burning down a line to clear a fault is considered valuable and justified in those cases of trouble where otherwise it would be necessary to hold the entire circuit out of service until the fault could be located and removed by other means. The purpose, therefore, was to prevent hazards associated with needless burndowns, or in other words, the burndowns that result from faults defined as transient. It is true that many other advantages accompany the solution of the main problem but in the present case these are inherent in the scheme of operation adopted and in the equipment developed; they work automatically to improve the service rendered to customers.

To review briefly, the power arc is the medium by which conductors are burned down. The destructive forces of the arc are dependent upon the magnitude of arc current and the duration of arcing. The current magnitude is fixed by the characteristics of the circuit and the location of the fault. The duration of arcing, however, is subject to control. Our research studies established the limits of the control required with covered wires to prevent burndown and to keep arc damage within admissible amounts. The solution of the problem, then, lay in providing means for initially interrupting the circuit in case of fault within the intervals of time established. As stated in the paper, these intervals range from about one-half to two cycles depending upon the size of wire and the arc current involved at the point of fault. One of the accompanying advantages referred to above is that this speed of initial interruption also prevents operation and damage to line fuses. In addition, it permits the location of fuses much closer to the power source without danger of unintended operation on transient faults.

It will be noted that all of this deals entirely with the initial interrupting time and is in no way involved with the reclosing practice. That is another matter. The one-half- to two-cycle initial interruption is designed to apply a safeguard against serious arc damage at the instant a fault is detected, and to keep the entire line intact whether covered or bare wire, sectionalizing fuses included, on the supposition that the fault may be transient. If the supposition proves correct, and indications are that a high percentage of faults are of this type, the hazard of a possible burndown will have been avoided, and in addition, the entire circuit will be returned to service upon reclosure. If, however, the fault proves to be persistent, the time-delay control brought into action upon reclosure will serve to burn the fault clear, if possible, as in present practice.

Turning now to Mr. MacNeill's opening remark, the author repeats that the chief aim of the investigation was not to improve radial distribution line service but to reduce wire burndowns and arc damage that would lead to mechanical failure of conductors. It naturally follows that if the number of wires down is reduced, service is automatically improved. With reference to the inadequacy of the speeds of conventional equipment, it should be made clear that reference to performance in terms of reclosing speed, or to use Mr. MacNeill's expression, in terms of total elapsed time from, "moment of short circuit until contacts retouch," is not indicative of ability or inability to prevent wire burndown. The breakers to which Mr. MacNeill refers have an over-all fault clearing time of the order of about ten cycles, two cycles of this time representing arcing within the breaker. This performance, as has been shown, is inadequate for the purpose under consideration.

In reviewing the paper, Mr. MacNeill points out that three devices were developed. This is true, but it is felt that his statement, that the units are operated by high-tension auxiliaries will be confusing to those not so familiar with the equipment inasmuch as the parts referred to as auxiliaries are integral parts of a self-contained mechanism.

With respect to the high-speed reclosing equipment and arc suppressers used 20 years ago, these could not be actuated to clear an arc in one-half cycle which has been found to be necessary if we are to prevent objectionable damage to the smaller sizes of conductors.

The author is familiar with many of the developments in high-speed reclosing equipment but points out that most of the attention has been given to speed of reclosing and not to the speed of opening the circuit to clear arcing faults. In this connection it might be mentioned that the shorting contactor with its own circuit-opening device is capable of not only one-half-cycle interruption but of restoring voltage in a total time as short as four cycles if desired in 7,500-volt breakers.

The statement that 80 per cent of all overhead line faults are satisfactorily cleared on a first reclosure and that thus present standard equipment is doing reasonably well, is not a measure of the number of cases of wires down. The 80 per cent figure checks the experience on the Detroit Edison system, but reference to table I in the paper will show that on that system there was still an average of 845 cases of wires down per year for the period 1938 through 1939. Our studies indicate that improvements cannot be made economically along conventional lines, using high-speed interrupters and available relays and trip coils. However, the shorting contactor used in combination with existing conventional switchgear, as described in the paper, will provide for the quick clearance of faults to reduce arc damage and the number of falling wires in an economical manner.

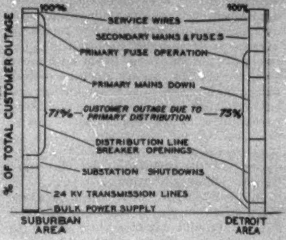

Figure 2

Mr. MacNeill refers in his closing remarks to advantages to be gained with increased restoration speed, a point he has made paramount throughout his discussion. It is the author's opinion that reclosing speeds that have been available in conventional equipment for some time (15 to 30 cycles) are quite satisfactory so that there is no problem along this line. The real need is for a speed of interruption which will save the overhead conductors from needless damage.

The author is enthusiastic over the suggestion of a symposium on this whole subject to bring out the operating requirements. This should prove helpful to all concerned. However, in order that a common understanding of all factors involved be made possible, it is recommended that care be exercised in the choice of terms and expressions used to bring out the picture. Terminology in this field is poorly defined and lacking in many respects. Effort directed toward standardization of methods for expressing the facts would, in the author's opinion, be well worth while.

Mr. Jeanne's comments concerning the advantageous effects on joint use of poles of reducing the number of distribution line failures is pertinent. The situation should be materially improved by eliminating the needless burndowns.

The data abstracted from the studies of the joint subcommittee on development and research are interesting indications of faults and their causes but, as given, the information is not sufficiently complete to permit a comprehensive analysis. Faults are defined, for that study, as disturbances having durations over about one cycle. This prompts one to question whether the results include, as faults, surges that under normal operating conditions might go unnoticed. The point the author wishes to make is that if our definitions of a fault do not agree, then any percentages based upon the number of faults will not be comparable and confusion and misunderstanding may result.

On the whole, Mr. Jeanne's remarks indicate that faster clearance of faults is desirable from the telephone engineer's point of view to reduce the number of interferences between telephone and power lines.

Mr. Jeanne and Mr. Sayles both inquire concerning the applicability of the devices developed to grounded-neutral systems. Used on such systems these devices will be as effective in interrupting arcs to ground as they are in interrupting phase-to-phase

Vol. 6
1941

arcs. There is no difference in the method of application except that in the case of the grounded system there must be one shorting contactor in each phase and the external short-circuiting connection between the devices must be grounded in order to shunt a phase-to-ground short circuit. Likewise, where the fast opening and reclosing breaker is used there must be a unit in each phase whereas in the ungrounded system two units suffice.

The results reported by Mr. Halperin of studies conducted several years ago in Chicago show that from the customer outage point of view service is already excellent. Similar figures were obtained in Detroit and if this were the only consideration involved we would not be justified in spending more money. However, as pointed out above, there are still too many cases of wires down.

Mr. Halperin reports 345 cases of trouble in the Chicago urban area during 1938 and 1939 involving primary wires burned down. On the basis of the reported 1,500 circuit miles, this amounts to 8.7 cases of burndowns per year per circuit mile. In the city of Detroit during the same period there were 703 cases of trouble involving primary wires down in 1,830 miles of circuit. Of these, 147 cases were attributed to an extraordinarily severe sleet storm. Eliminating these from the total of 703 we get 556 cases. If we neglect that the cause of some of these cases was mechanical interference, and assume that all 556 cases were the result of burndown, we obtain 6.6 cases of burndown per year per circuit mile for Detroit as against 8.7 for Chicago.

Since Mr. Halperin's comments refer only to urban territory, for which only one of the devices developed, namely the shorting contactor, would be economically applicable, it is assumed that his stated lack of enthusiasm does not extend to the field for which the fast opening and reclosing breaker is intended which is chiefly suburban and rural.

Mr. Lincks asks the relationship between the number of cases of wires down, as shown in table I in the paper, and the total number of outages occurring on the system during the same period. Outage data for the years 1938 and 1939 do not happen to be readily available in convenient form for a direct comparison but the accompanying chart, figure 2, shows for the period 1933 through 1936 the types of relationship in which Mr. Lincks is interested, but we do not believe it to be different from the period. These data have been divided between the Detroit area and the suburban area and in each case the percentage of the total outage chargeable to the different parts of the system is indicated. As noted, the data include all outages over five minutes in duration. It can be seen that for the Detroit area 75 per cent of the outage was due to primary distribution troubles, wires down accounting for something close to one-half of the 75 per cent. The corresponding figure for the suburban area is 71 per cent, wires down again accounting for about a half. This type of classification of outages, as has been pointed out frequently in the past, shows that the distribution system is the weakest link in the conducting path between power plant and customer.

With reference to the growth of distribution circuits beyond the orbit of the station breaker and its overcurrent protective relay, it may be mentioned that the shorting contactor installed out on the line can be set low enough to trip on faults at the end of the line and still be within the range of load currents at its point of installation. When the shorting contactor operates it will increase the fault current sufficiently to cause operation of the station breaker. This explanation also answers one of the points raised by Mr. St. Clair.

Mr. Lincks states that in these days of increased use of automatic opening and reclosing, and now, short-circuiting equipments, we should not overlook the fact that interruptions, no matter how short, may cause unfavorable psychological reactions on the part of the customer because of the telltale on the electric clock. It is assumed that this refers to the probable greater number of openings to be expected with instantaneous trip than with time-delay initial opening.

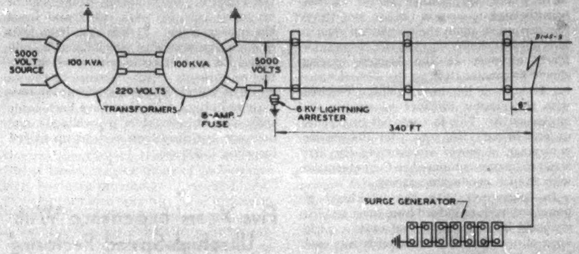

Figure 3. Arrangement used for surge flashover tests on a 5,000-volt line to determine the presence of 60-cycle power-follow current

The presence of 60-cycle current following a surge flashover on the line was ascertained by the color in the arc and the blowing of the eight-ampere fuse

Several years' experience on the Detroit Edison system with some 25 circuits equipped with instantaneous relays, and two years' experience with two circuits equipped with shorting contactors, show that the number of customer interruptions with this system of operation is not objectionable. It is the author's opinion that in going from time-delay to instantaneous tripping on fused circuits equipped with conventional switchgear there is not the increase in interruptions that might be expected because of the fact that the fuses blow on transient faults. When such circuits are equipped with the newly developed high-speed interrupting devices the decrease in customer outage due to protection fuses and covered wire against transient faults will greatly outweigh any disadvantages due to increased momentary interruptions. As a matter of fact, the author believes that the psychological reaction of the customer will be favorable rather than unfavorable when he sees the rapid restoration of service notwithstanding a greater number of interruptions.

Mr. Kidder states that his experience suggests that lightning flashover of line insulators is almost innocuous at four kilovolts and he attributes this to the likelihood that power arcs will not be ignited by a flashover where the path is greater than five inches per kilovolt of operating potential. He gives a reference to the paper by H. N. Ekvall, entitled "Lightning Protection of Medium-Voltage Lines," from which it is understood that the figure of five inches per kilovolt is based on the length of the arc-over path measured along the surface of the supporting structure rather than between the phase wires in air. On this basis the corresponding figure for The Detroit Edison Company's 5,000-volt distribution system, which uses a minimum 28-inch conductor spacing, is about eight inches per kilovolt. In view of this fact and because the majority of wire burndowns on this system occur during electrical storms it was thought advisable to make tests in our surge laboratory to verify the applicability of Mr. Kidder's experience to the Detroit conditions. A description and the results of the tests follow.

A diagram of the test setup is shown in the accompanying figure 3. Standard crossarms with wood pins and porcelain insulators were used. The conductors were number 6 covered wire. As indicated, the lead from the surge generator was connected about six inches from one of the crossarms. The generator rating is 700 kv, 12,000 amperes, and the rate of voltage rise used was 1,600 kv per microsecond. The estimated time required to dissipate the 12,000 amperes was 30 to 50 microseconds. The eight-ampere fuse was connected in the circuit on the source side of the lightning arrester to clear the circuit of fault current in the event of power arc-over. Maximum fault current, at the point of flashover was measured and found to be 240 amperes. In order to simulate conditions during an electrical storm the crossarm near the surge generator connection was sprinkled with water before each test.

In the first tests the conductor spacing was 14 inches in air which gave an arc-over distance over the wood insulation equivalent to five inches per kilovolt at the 5,000-volt phase-to-phase potential used. In nine out of ten tests power-follow current caused operation of the fuse to clear the circuit. The blowing time of the eight-ampere fuse with 240 amperes is six cycles. In spite of the proximity of the discharge to the wet crossarm, flashover in all tests took place in the air space between conductors without touching the crossarm. It appears therefore that the method of calculating inches per kilovolt from the length of the flashover path along the crossarm might be open to question.

In the next series of tests the conductor spacing in air was increased to 28 inches which gave an arc-over distance over wood equivalent to eight inches per kilovolt. In this series 60-cycle power-follow current caused fuse operation in 10 out of 38 tests. In 20 of the 38 tests it was noted that flashover took place directly between the phase conductors and in the remaining 18 tests the flashover followed a path along the crossarm.

In these tests no attempt was made to co-ordinate the application of the surge impulse with the 60-cycle wave. The percentage of cases in which the impulse was superimposed at a point on the 60-cycle wave where the voltage would be sufficiently high to sustain the arc was therefore dependent upon the element of chance. It is obvious, however, that the chances for power arc-over at the 14-inch spacing should be greater than at the 28-inch spacing because of the lower voltage required with the shorter distance to sustain the current path. This factor is felt to explain, at least in part, the reason for the greater percentage of power arc-overs in the first series of tests as compared to the percentage with 28-inch conductor spacing.

In connection with the likelihood of power arc-over, as judged from these results, it should be understood that only a single wave of not over 50 microseconds was used in each test, whereas, in actual service the lines are frequently exposed to lightning waves having durations of the order of 100 to 200 microseconds which greatly increase the probability of power arc-over.

It is indicated by the results of these tests that the figure of five inches per kilovolt or even eight inches per kilovolt is not sufficient to be effective at an operating potential of 5,000 volts. Our operating experience at 5,000 volts also shows that eight inches per kilovolt does not give freedom from power arc-over due to lightning.

The curve data presented by Mr. Kidder pertaining to the total time required to sever covered wire and for the accompanying arc to be extinguished at 2,500 volts is of interest in connection with considerations of the time required to clear persistent faults.

Mr. Sporn's remarks are illustrative of the way in which our conceptions change as time goes on and more factual data and experience are accumulated. The author agrees with the statement that other means can be developed for accomplishing the main objective under discussion, namely, reduction of wire burndowns. It might be added that many important factors enter into the choice of means for the solution of this problem. One of these is the desirability of making the most of investments we already have in lines and equipments. Another is the desirability of taking advantage of any opportunities to help other situations while dealing with the chief point of issue. In the last analysis the best solution is that which gives the greatest over-all benefits consistent with a cost that is economically justified. The solution adopted in this case was chosen after carefully weighing consideration of this character.

Mr. St. Clair questions the extent to which the problem under discussion has been affected by the nature of the system involved, pointing to the fact that the Detroit system is of the ungrounded type. Since both grounded and ungrounded systems are subject to the same exposures it is felt that Mr. St. Clair has answered his own question by stating that a fallen conductor on a grounded system does not insure sufficient flow of fault current for relay action as has been demonstrated many times.

Mr. Blake's remarks that the primary system is the place to spend money to realize a substantial reduction in outage to the consumer is well borne out in the chart previously referred to as figure 2.

To Mr. Elzi's question as to whether the time-delay tripping device of the high-speed opening and reclosing breaker can be set to be selective with relays and fuses, the answer is yes. Means have been built into the equipment by which it can be calibrated for co-ordination with other protective equipment. With reference to the increase in voltage surges accompanying two-cycle switching, tests that have been made show no objectionable overvoltages and none are anticipated on systems up to and including 7,500 volts.

Five Years' Experience With Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines

Discussion and authors' closure of paper 41-52 by Philip Sporn and C. A. Muller, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 241–6.

Eric T. B. Gross (College of the City of New York, N. Y.): In order to appreciate the advantages brought about by the application of ultrahigh-speed reclosing, we should compare the results obtained by the use of this device with the results obtained using similar remedial measures which are also designed to minimize the effects of faults. It seems to me that the earth-fault coil is the only device which can properly be compared with ultrahigh-speed reclosing. The term "earth-fault coil" is used to designate any single- or three-phase reactor which is designed and installed in such a way as to balance the charging current to ground of the network. These coils have been sometimes called by the names of their inventors, namely: Petersen, Jonas, Bauch, Reithoffer.[1] Of course, earth-fault coils are applicable in transmission and distribution systems only where the insulation level of the transformer star points is equal to or greater than phase voltage.

By ultrahigh-speed reclosing is meant the interruption of the arc current by opening the switches and keeping them open as long as necessary for the deionization of the arc. Earth-fault coils accomplish the same result, in the case of single line-to-ground faults, without the opening of any switch whatsoever. The arc current is quenched by the coil current and the very slow recovery of the voltage at the point of the fault allows the ionized air to disperse and thereby prevents restriking.

We may, therefore, compare the results of operation of the two methods of protection under similar fault conditions, namely single line-to-ground faults. Of the 71 flashovers mentioned in the paper, 55 or 77.5 per cent were single line-to-ground faults, which certainly would not have introduced disturbances if earth-fault coils for permanent operation had been used, provided the coils were properly designed and tuned. On the other hand, in 91 per cent of all cases, the ultrarapid reclosing was successful, so that the practical gain of this device is 13.5 per cent = 91 per cent − 77.5 per cent. The question remains as to whether it pays to introduce ultrahigh-speed reclosing to obtain this additional 13.5 per cent. Of course, in networks with solidly grounded neutrals, earth-fault coils cannot be used, and there remains only ultrahigh-speed reclosing. Furthermore, ultrahigh-speed reclosing can, in addition to earth-fault coils, be used to advantage in systems with resonant neutral grounding, to take care of the few shorts which occur between two and three phases.

It seems to me that in the medium voltage systems, such as the 22,000- or 33,000-volt systems, mentioned by the authors, earth-fault coils can be used even more advantageously. Particularly in radial systems, or systems having a small number of points of supply, the earth-fault coils can almost always be added without extensive system changes. I do know from practical experience with radial and network systems in Great Britain,[2] and Continental Europe that in all the faults that occur, the percentage of faults extinguished by the action of the coil is, on the average, between 85 per cent and 90 per cent. For example, in the case of a 290-mile, 23,000-volt mesh-type system in Czechoslovakia, in which most of the lines are without ground wires, the number of interruptions during a period preceding the installation of earth-fault coils (1923) was 183. Though the mileage had increased, in the corresponding period of the following year, after the coils had been put into operation, the number of outages was only 22. This means a reduction in interruptions of 88 per cent. It seems to me that the earth-fault coil is the perfect solution to the problem for subtransmission and distribution networks. I doubt very much that the cost of the high-speed relaying and reclosing equipment for such systems can be made competitive with the cost of earth-fault coils, except perhaps in systems where locating and isolating the few permanent faults introduces great operating difficulties.

J. W. Jones (Philadelphia Electric Company, Philadelphia, Pa.): The five-year record with perfect mechanical performance and 91 per cent successful reclosure, including some double-line faults, is a remarkably fine showing indicating establishment of the reclosing time on a satisfactory basis and perfection of breaker operating mechanism.

It is interesting to note that the proportion of one-, two-, and three-phase faults is practically the same as experienced on the Pennsylvania-New Jersey 220-kv system which in nine years' experience involving 194 faults, had 82 per cent one-phase, 11 per cent two-phase, and 7 per cent three-phase compared with 81, 11, and 8 per cent, respectively, in the paper.

Performance of the high-speed reclosing might not have been so satisfactory if used on lines operating closer to the stability limit, or on systems in which the power sources and load were not so well distributed.

There was apparently little need for high-speed reclosing in many of the operations. The oscillograms show no sign of instability or serious voltage disturbance after the initial trip-out and in many cases the lines could probably be kept out for the short time required to permit reclosing by the operator. However, there are a few cases of double-line faults, as illustrated by oscillogram 4, in which the high-speed reclosing was undoubtedly a distinct advantage.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The outstanding record for high-speed reclosing as summarized in the paper by Messrs. Sporn and Muller should lend heartening encouragement to those concerned with obtaining the most from their transmission systems. The successful performance is undoubtedly due to the emphasis that has been put on speed of clearing and reclosing.

A major part of the system described in the paper, consists of double-circuit lines bussed together at comparatively short transmission distances which lend themselves particularly well to quick relaying, switching, and reclosing, as a minimum of shock to the system results from the quick switching out of any one of the parallel sections in the case of a single-circuit fault. However, successful reclosures even for single-circuit faults of double-circuit lines allow for a further increase in the line loading for a given number of intermediate stations if the operation is sufficiently quick, approaching as a limit the steady-state stability limit of two circuits.

The data given indicate that the probability for double-circuit faults is small with quick clearing. The double-circuit faults are likely to be most severe from a stability standpoint and also from the reclosing standpoint if the circuits are on the same tower. It is of considerable importance, therefore, to note that out of eight double-circuit faults, six reclosed successfully. It would be of interest to know if the two double-circuit faults which restruck, restruck on both circuits. If reclosure in such a case is successful even on only one circuit, it may be possible to retain synchronism between the two temporarily separated parts of the system. The chances for success would be influenced, among other factors, by the separation between the parallel circuits and the distance between intermediate switching stations which determine the length of single-circuit line left holding the system together.

A goodly percentage of successful double-circuit reclosures indicates even more definitely, than do the single-circuit reclosures of double-circuit lines, that quick reclosure allows an increase in what can be considered the reliable loading of the system. It would be of interest if the authors could give data to indicate the loads being carried at the time of reclosure.

There are factors which make quick reclosure desirable even if synchronism is lost. One of these, the possibility of pulling into step, has been previously mentioned. Another factor which may become of increasing importance, is that it reduces the possibility of separation except at points previously selected in case a sustained system out-of-step condition exists. This makes possible a more flexible generating schedule, in that generating capacity may be more accurately and easily allocated with load in case of a separation.

Rapid reclosure on the single-circuit lines is of particular importance because there exists no parallel circuit to keep the separated parts of the system in synchronism. From a stability point of view they might well be classified with the double-circuit faults of a double-circuit line. It would be of interest to know if there is any distinction between the experience obtained on double-circuit lines as compared with single-circuit lines.

David C. Prince (General Electric Company, Philadelphia, Pa.): One undertakes a great many projects which seem very important at the time but which after five years are so completely forgotten that one has to search the files to find out what the excitement was all about.

The record of ultrahigh-speed reclosing is a conspicuous exception to such experiences, and I regard with a great deal of satisfaction the fact that I was privileged to be in on the ground floor of the experiment, the success of which is recorded in this paper. Those who have been regular attendants at AIEE conventions know that no subject has received more study in more different ways than that of maintaining continuity of service over long-distance transmission lines. Safeguarding continuity has been studied from a number of different angles, including the use of ground-fault neutralizers, expulsion gaps, grounding systems, and overhead ground wires, parallel lines, etc., in addition to the ultrahigh-speed reclosing covered by this paper.

Ultrahigh-speed reclosing presents one important difference compared with any of these other methods of attack. It is always necessary to have circuit breakers and relaying equipment regardless of what other means may be employed in addition to reduce lightning outages. High-speed reclosing does not inherently require additional apparatus but only that the apparatus which is there in any case be designed for this exacting service.

The largest unknown in connection with ultrahigh-speed reclosure had to do with what actual experience would show. It was possible to determine by laboratory methods as reported in the earlier paper referred to by the authors that there was a certain probability of restrike, and what it depended upon. The unknowns had to do with the occurrence in nature of such restrikes. It was not possible to predict whether multiple lightning strokes, for instance, would actually cause many more restrikes than anticipated from laboratory tests or whether, on the other hand, the presence of wind might give a very much smaller number of restrikes.

Now we have the record before us, and as the authors have stated, the operating results have been superior to expectations. This opens the way to increased continuity of service by relatively simple and inexpensive means in a short time. This may be very valuable in the light of our present national emergency, during which it is even more important than in normal times to keep the wheels of industry turning by continuous electrical service.

E. E. George (Ebasco Services, Inc., New York, N. Y.): The paper by Messrs. Sporn and Muller presents the experience record of a very important contribution they have made to the operation of high-voltage interconnected systems. This work has been greatly facilitated by the efforts of the manufacturers in speeding up the operating time of relays, tripping mechanisms, and closing mechanisms.

It is interesting to note that two obstacles originally suggested as limiting the field of high-speed reclosing have not been found in practice to be as serious as was first suggested. A few years ago it was suggested that multiple lightning strokes occurred frequently enough and with proper timing to prevent successful high-speed reclosure in an important percentage of cases. The experience of the American Gas and Electric Company on 132-kv ultrahigh-speed reclosing and of many other transmission companies with immediate reclosing indicates little difficulty from multiple lightning strokes.

Upon the advent of immediate reclosing the manufacturers prepared a derating table for use in connection with immediate reclosing cycles. This table without substantial change is still included in the manufacturers' latest catalogues for use in selecting new breakers as well as in determining the capability of existing breakers. For the instantaneous automatic reclosing cycle a "nonoil-tight" breaker is derated to approximately 30 to 50 per cent of the normal two-minute rating and an oil-tight breaker to 85 per cent or less of the 15-second rating. This derating table has resulted in many companies being slow to take advantage of immediate reclosing for fear of blowing up a large number of their existing circuit breakers, or in lieu of this, being forced to replace them with much larger and more expensive breakers. There is sufficient operating experience from transmission systems by this time to show that this derating table must have some elements of only academic or commercial interest. The table has not been substantiated by operating experience with immediate reclosing. It is interesting to note that Messrs. Sporn and Muller make no mention of breaker derating as a deterrent factor in their plans for ultrahigh-speed reclosing.

Perhaps one of the joint committees might look into the matter of deratings—from the standpoint of operating experience.

L. R. Ludwig (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The problem of reducing transmission line outages, particularly due to lightning, has been tackled by at least four different methods; namely—

1. Overhead ground wires.
2. Installation of protector tubes.
3. Petersen coils.
4. High-speed breaker reclosing.

The authors of this paper have tried several of the above means, and their further comments regarding the relative merits of the various ones would have considerable value.

The paper does not specifically set forth a recommended time for circuit reclosure after completion of the interruption, and their further comments would be appreciated. In this connection, does the interrupting time seem to have any effect on the subsequent reclosing time, other than in possibly preventing a two-line flashover?

There is a growing interest in clearing single-line transient faults by opening and reclosing one pole of the breaker only. Do the authors have any data or recommendations as to this procedure?

The successful use of high-speed reclosing breakers is of great interest to the manufacturers, and the Westinghouse company has done considerable work with various forms of mechanisms and breakers for this service. Motor-operated reclosing mechanisms for 20-cycle over-all operating time have been built and placed in service. A compressed-air mechanism for oil breakers has also been developed and will shortly be in service. This device can be made very fast, it is simple, and particularly attractive because high operating forces are so easily obtained. An air cylinder and piston are used to close the breaker and the opening is by means of a spring in order to make interruption independent of failure of the air system.

Percy H. Thomas (Federal Power Commission, Atlanta, Ga.): The concise and complete statement of the facts offered and conclusions drawn makes questions put to the authors largely superfluous. On the other hand, the very concreteness of the results may make practicable the drawing of conclusions upon which important action can be based. For example, if in an exceptionally exacting situation like that of the operations described, 90 per cent of the lightning and homologous flashovers can be safely handled by quick-acting, self-closing breakers, does it follow that the extreme precautions now often taken to make lines lightning-proof may be relaxed, and materially cheaper construction used? If so, the advance achieved is of momentous importance and a notable event.

There have been many improvements in engineering designs and apparatus looking to more continuous and effective service, but very seldom does any new safety device seem to result in elimination of other and prior safeties with the lowering of cost and decrease of complexity.

The author has before pointed out the great saving in cost and relief from complication that would result in utility operations if each link in the system had an alternate, automatically cut in by trouble on the link, provided such relief, by shift to the alternate, be frankly relied upon and no extraordinary construction be attempted to make any link invulnerable. This high-speed, quick-acting breaker serves much the same purpose to the extent that it renders alternative protective expense unnecessary. It goes without saying, however, that no immediate general dropping of safeguards would be appropriate just because of a new protective means. The suggestion is that this idea of simplification be used as a guide with the purpose that a gradual evolution would result in ultimate economic gain.

Apparently there is a distinct difference in arc interrupting conditions between one case in which all phases of all transmission circuits connecting two centers are involved in a short, and a second case in which only a portion of the circuit phases connecting the centers are involved in the arc, or in which only grounds from some phases are involved. I would like to ask the authors whether they can trace a difference in kind in the operations of the quick-acting breakers between these two cases. Does the existence of some alternative paths for the flow of some energy in parallel to the arc constitute a necessary basis of success?

No statement is made in reporting these results whether any difficulty was met in any of the cases from the loss of synchronous apparatus.

Has any effort been made in these reported cases to connect the degree of success in arc suppression with the magnitude of the short-circuit current, as determined by total synchronous capacity and line impedance?

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): In addition to the several reclosures discussed by the authors and illustrated by oscillograms, there have been reclosures at other points on the system which are of considerable interest and I should like to discuss four of these.

Referring to figure 1 of the authors' paper, the location and relation to the rest of the central system of the lines which I shall discuss can best be seen from figure 1 of the authors' paper. These are:

1. The Philo-Howard double-circuit 132-kv line which forms an important tie line between the central and western section of the central system.
2. The Saltville-North Bristol line which is a part of the single-circuit line which interconnects the central system with a portion of the system of the Carolina Power and Light Company.
3. The Roanoke-Fieldale line which is part of the line interconnecting the central system with a portion of the Carolina Power and Light Company.
4. The Roanoke-Reusens double-circuit line.

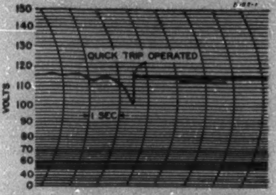

Figure 1. Voltage at Kingsport during ultrahigh-speed operation on the Saltville-North Bristol line

PHILO-HOWARD LINE

Over the past few years there have been a number of double-circuit outages on the Philo-Howard line. These invariably caused the Canton-Ashland-Howard line to trip, with the result that the central and western portions of the central system were split apart. While this did not result in any service interruptions to any part of the system, it did usually upset loading schedules to a considerable extent. In order to improve operating conditions, ultrahigh-speed reclosing was installed on these circuits in 1940. Since the installation date, there have been no cases of double-circuit trouble. However, there has been one case where number 1 circuit was out of service and lightning struck the number 2 circuit during this period. At that time approximately 70,000 kilowatts was being delivered from Philo to Howard over this single circuit. The line tripped and reclosed successfully. It is therefore felt that even with heavier loads on the line, in case of double-circuit outage reclosure will be entirely satisfactory.

SALTVILLE-NORTH BRISTOL LINE

Figure 1 shows the voltage record at Kingsport during a successful reclosure on the Saltville-North Bristol line. This indicates that the voltage was restored in approximately one-half second. This circuit is a section of the 150-mile line extending between Switchback and Waterville, 64 miles of which operate at 110,000 volts and the remainder at 132,000 volts with a 55,000-kva 132/110-kv autotransformer at Kingsport. There is a 7,500-kva condenser at Kingsport, a 9,000-kva condenser at Saltville, and an interconnection at North Bristol with the East Tennessee Light and Power Company. This latter company's system normally has 15,000 to 20,000 kw of generating capacity, most of which is hydro. During this case of trouble there were three 45,000-kva units in operation at Waterville. These units were carrying some 40,000 kw of local load and 55,000 kilowatts was being transmitted to Kingsport, about 48,000 kw of which found its way over the North Bristol-Saltville section of the line.

The point of interest in connection with this is that calculations indicated that during periods when Waterville hydroelectric plant was connected only to a small

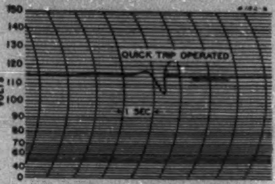

Figure 2. Voltage at Roanoke during ultrahigh-speed operation on the Roanoke-Fieldale line

local load and the central system it was doubtful if reclosing would be successful due to the line capacity and the relatively low inertia of the hydro units at Waterville as compared to that of the large predominantly steam system to the north. Regardless of the paper study, it was decided to install ultrarapid reclosing on the Saltville-North Bristol line and the North Bristol-Kingsport line. In the case just cited there was considerable local load at Waterville, nevertheless, experience indicates that reclosure would be successful even if this local load were small.

This line has also reclosed successfully with the Waterville line open, with the result that no load was lost at Kingsport, North Bristol, or Saltville and that the 7,500-kva condenser at Kingsport pulled in satisfactorily. The operation of both these sections of line indicates that ultrahigh-speed reclosing can be successfully applied to a setup of this character.

ROANOKE-FIELDALE LINE

Figure 2 shows a voltage record during a successful reclosure on the Roanoke-Fieldale line. Here again, the record indicates that voltage was restored to normal in about one-half second. The load being transferred across the line at the time was 25,000 kw. This line section is 37.5 miles in length. The distance from Roanoke to the nearest generation on the Carolina Power and Light Company system is 193 miles. It will be noted from table I of the authors' paper that the ultrahigh-speed reclosing equipment was installed in April 1940, and during the remainder of the year there were 12 reclosures, all of which were successful.

It is realized that the question still remains as to whether the arc will extinguish sufficiently fast to allow reclosing if synchronous equipment is connected at some point on the line. Our only experience has been in connection with the Roanoke-Reusens number 2 circuit. This line is tapped at about the mid-point and connects to a small system having a hydro plant of 1,200-kva capacity and with considerable synchronous load. It will be noted from table I of the paper that this line did not fail to reclose in the three cases experienced since the installation of ultrahigh-speed reclosing.

The application of ultrahigh-speed reclosing on the 132-kv lines of the central system of American Gas and Electric Company has made possible a higher degree of service continuity, the optimum use of generating facilities, both from the standpoint of bulk power transmission and from the standpoint of most economical loading of plants. It has also made possible more efficient use of interconnections with foreign companies.

Philip Sporn and Charles A. Muller: Mr. Thomas has raised a point which is sometimes neglected as advances are made in engineering practice; namely, that when an improvement is made to overcome a specific problem other improvements previously made for the same purpose should then be reconsidered in the light of the new development to see if their continued application is justified. It is the authors' belief that the advances which have been made in lightning protection of lines cannot be generally discontinued as a result of the use of ultrahigh-speed reclosing but that it may be possible to drop a few specific practices with a consequent reduction in costs. The points which must be kept in mind are that any such omissions must not increase the total number of permanent faults and that the increase in cases of lightning flash-over and resultant voltage dips must not affect the general system operation adversely.

The only basic difference between a fault involving all phases of all circuits connecting between two centers and one in which only grounds from some phases are involved, is that in the latter case some energy can still be transferred over the sound conductors, helping to retain synchronism. In this case, of course, the theoretical maximum power which may be delivered without loss of synchronism is increased. The gain, however, is small, since the power flows only until the circuit breakers have opened, which occurs in a maximum of nine cycles after the inception of the fault, and there is actually no practical difference in the success of reclosures involving trouble on one, two, or three phases. In the case of a fault of any kind on a single circuit of a double-circuit line there is, of course, a definite gain in the maximum power which can be transmitted, since in this case the sound line provides a path for continuous transmission of synchronizing power.

Aside from the question of maximum power which may be transmitted, the experience so far indicates that there is more chance of a fault restriking when more than one phase is involved. It is hoped that the development of breakers having faster clearing time will help to eliminate this difficulty by permitting a longer de-energized time with the same over-all reclosing time.

No difficulty has been experienced at any time with the loss of synchronous apparatus during reclosing operations.

Mr. George has brought up the question of derating breaker interrupting capacity when used for immediate reclosing and has pointed out that the manufacturers' latest catalogues still derate a breaker to 30 to 50 per cent of its normal 2-minute rating and to 85 per cent or less of its 15-second rating. It must be remembered that the two-minute rating applies only to old non-modernized breakers and a few low-capacity low-voltage breakers currently listed. Because of the duty imposed on breakers used for ultrahigh-speed reclosing, these breakers are always modern or modernized up-to-date types and are rated on a 15-second basis. For the 138-kv 1,500,000-kva breaker which has been used in most cases, the rating factor for immediate reclosing is 85 per cent of the 15-second rating. So far this has not represented any serious handicap, since interrupting duty has in all cases been well below this value. However, the accumulation of field experience over a period of time with this new method of operation may quite possibly furnish a basis for liberalizing even present derating factors.

Mr. Crary has brought out the important question of line loading at the time cases of double-circuit trouble occurred on lines connecting two centers or single-circuit trouble in cases where only one line existed. Most of the operations have occurred when these loadings were relatively light and there was no evidence of instability. However, Mr. Marquis' discussion has covered a few cases where these loadings were heavier, and it will answer Mr. Crary's question. In both cases listed in the paper where double-circuit faults restruck, the restrike occurred on both circuits.

Mr. Marquis has described the system loading conditions which represent the most severe requirements under which the ultrahigh-speed reclosing has so far been called upon to operate. They show very clearly the valuable contribution which this development has already made to reliable system operation and indicate that considerably more severe conditions may exist before the limits of successful operation are reached.

We believe that the operations Mr. Marquis has described for the Saltville-North Bristol line illustrate the question Mr. Jones has raised regarding successful operation when power sources and load are not well distributed. This was regarded from the beginning as one of the locations where there was most likelihood of unsuccessful performance, and it has been very gratifying to note the results that have been so far obtained.

With reference to Mr. Ludwig's question as to recommended time for circuit reclosure, the time which has been used has been 18 cycles from energization of the trip coil to re-energization of the line. This means that for 8-cycle breakers the line is de-energized 10 cycles and for 5-cycle breakers the line is de-energized 13 cycles. At the time the first ultrahigh-speed reclosing installation was put in service on the Ft. Wayne-Deer Creek line, tests were made to obtain data on minimum de-energized time permissible. These indicated that restrikes occur for one-phase-to-ground faults when the de-energized time is reduced to 6 cycles, and that they occur for phase-to-phase faults after as much as 12 cycles de-energized time. There has been no indication from operating experience as to whether interrupting time has any effect on the subsequent de-energized time required. However, there is some indication from laboratory tests as reported in the paper by Sporn and Prince published in the AIEE TRANSACTIONS, volume 56, pages 81–90, that a definite relation exists between these factors.

The authors have had no experience with clearing and reclosing line transient faults by single-pole breaker operations but will be very much interested in data on results which are obtained with this method of operation.

The question that Mr. Ludwig raises as to the relative merits of various methods of reducing transmission line outages is, of course, one of the important questions in transmission system design and operation. It is obvious that of the four methods of combating the effects of lightning, one is of a preventive nature and the other three are all remedial. As regards the preventive measures, the use of the overhead ground wire has become so well established from a technical standpoint that there doesn't seem to be any question that any important transmission line of even moderately high voltage cannot be considered to be properly designed unless provisions have been made for its proper use. This means not only a design of tower structures to give proper arrangement of conductors and of ground conductors, but also the concomitant devices such as proper grounding and/or counterpoise facilities. The authors are definitely in favor of carrying out on every project that much preventive work but all within economic limits.

Of the three remedial devices, the protective tubes covered a period in the study of the lightning problem and the working out of remedial devices in which they seemed to offer one of the few practical means of combating the effects of lightning flashover. Experience with protective tubes, particularly on high-voltage lines, over the last half a dozen years on the systems with which the authors are associated, has thrown serious doubt, not so much on the adequacy of the device as on the economic soundness of it. This is particularly so in the light of the generally unsatisfactory experience from a life standpoint with protective tubes of various kinds, including straight fiber, fiber-Herkolite, and fiber-Micarta-Herkolite combinations.

The Petersen coil has found considerable application on transmission systems in Europe but in analyzing the reason for its general nonacceptance in the United States, one needs to keep in mind first, the historic development of American systems which have always tended from the very early days to solid-grounded operation, and second, the difficulty that the Petersen coil offers to system operation, particularly in a situation where growth and development is experienced and where system switching may change from day to day and from month to month. This was not found to be a great handicap in European practice but in general it would appear as if the electric systems on which the Petersen coil was applied had more of a static character as regards growth and expansion than most American systems. Further, from a cost standpoint the Petersen coil undoubtedly involves greater expenditures, both in initial cost and in maintenance than the solidly grounded system utilizing high-speed reclosing. The latter obviously requires comparatively little change in the normal switching facilities and as those facilities become more modern, requires almost no change at all since standard modern switching equipment with standard modern relaying provide between them all the necessary facilities to make ultrahigh-speed reclosing possible. It has been the authors' experience that the latter, that is, ultrahigh-speed reclosing, has proved to be the one remedial device superior to all others on high-tension transmission circuits.

The points that Dr. Gross raises in connection with the Petersen coil are covered in the discussion given above on the points raised by Mr. Ludwig.

The authors share with Mr. Prince his feeling of gratification at the development of such satisfactory experience with ultrahigh-speed reclosing. They want to take this opportunity of acknowledging Mr. Prince's contribution to the early development of ultrahigh-speed reclosing.

Surges on Chicago 12-Kv System

Discussion and author's closure of paper 41-51 by F. O. Wollaston and H. J. Plumley, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 260–5.

R. C. Van Sickle (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have made a very valuable contribution to our data on system overvoltages. That these data have been collected systematically over a period of years is especially noteworthy. It practically eliminated the question of whether chance produced the worst possible conditions, a question which is left open by field tests due to the necessarily limited amount of data obtained on them.

The surge voltages which were measured were certainly lower than the worst possible combination of events might have produced. They were explained by the phenomena of the application of faults and the simple opening of circuit breakers without restriking. More complicated phenomena surely occurred also and, although capable of producing higher voltages, evidently did not. As pointed out by the authors, the overvoltages on the Chicago system did not exceed those which could be explained without assuming restriking. These data, therefore, support a paper and another discussion presented by me at the winter convention in 1939. At that time I showed oscillograms which illustrated how circuit breakers by their dielectric characteristics tended to limit the magnitude of the switching surges. One oscillogram of a 220-kv charging current interruption showed seven restrikes, with the maximum voltage reaching less than was theoretically possible with two restrikes.

The large capacitances of the cables caused the natural frequencies to be low for the single line-to-ground faults which were studied. They may account also for the apparent failure of the surges to pass through the transformers.

C. Concordia and H. A. Peterson (General Electric Company, Schenectady, N. Y.): In the past few years several papers discussing system overvoltages have been presented before the AIEE. These have led to an increased understanding of the phenomena involved, and have in several cases explained specific instances of damage to equipment. These papers have been based principally on calculations, although as far as possible they have been confirmed by tests and field experience. Such field experience is extremely valuable, especially in evaluating the relative importance and probability of occurrence of the various theoretically possible forms of overvoltage, and thus also helping to guide future investigations. We are therefore very glad to see this summary by Messrs. Wollaston and Plumley of overvoltage records of the past 20 years on a large system. It is particularly gratifying that the conclusion derived from theoretical investigations[1] (that for systems grounded through resistance or reactance, the maximum transient voltage normally associated with fault application may be taken as a good measure of the maximum switching surge voltages to be expected) is substantiated by this record of field experience.

Moreover, tests on miniature systems corresponding closely with the one under discussion have indicated that under controlled conditions, the maximum voltages to ground that can be obtained as a result of routine switching and ordinary fault conditions is on the order of four times normal line-to-neutral crest voltage. This is in very good agreement with the upper limit of 3.5 indicated in the paper, since the probability of encountering the very worst combination of circumstances is very small.

The relative importance of the various peculiar and special phenomena which may result in high voltages on some systems is not merely proportional to their relative frequency of occurrence. On the other hand, study of cases which have resulted in damage has convinced us first, that it is more often than not those situations that are unusual and special which result in equipment failures, and second, that these dangerous situations are not always easily recognizable without careful consideration and analysis.

There is one question that we would like to ask in connection with this paper. Since presumably sphere gaps and insulation failures were generally at different locations, is it possible that voltages which caused failures at a given location were higher than those indicated by sphere gaps at another location, and perhaps somewhat higher than 3.5 times normal?

ARCING FAULTS IN POWER SYSTEMS, C. Concordia and H. A. Peterson. AIEE TRANSACTIONS, volume 60, 1941, pages 340–6.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): In connection with conclusion 7 of this article, we know definitely that at least secondary failures are due to overvoltages. Examination of cable and joints that have been secondary failures in each case shows that the insulation was in poor condition, that is, for example, the sheath had been cracked at the duct and exposed the cable insulation. The point I want to make is that cable and joints of present-day design and material that are properly installed are not appreciably affected by transient overvoltages on underground systems. This point, so far as surges are concerned, is substantiated by the fact that the impulse strength of impregnated paper insulation is, according to tests reported by others, equal to at least 1,400 volts per mil of total thickness.

J. M. Dunham (Bell Telephone Laboratories, Inc., New York, N. Y.): In connection with the work of the joint subcommittee on development and research, Edison Electric Institute and Bell Telephone system, on fault current limitation, investigations of overvoltages and fault resistance have been carried on over a number of years. Overvoltage observations on systems grounded through resistance or reactance have been supplemented in some cases by staged tests. These tests included both solid and arcing line-to-ground faults, and measurements of overvoltage. Although the neutral impedance has in most cases been higher than that on the systems described by the authors, there is a similarity between their data and that obtained by the joint development and research subcommittee. In general, our observations have shown maximum overvoltages occurring at or near the initiation of the fault and of essentially a low-frequency nature. Also, about the same discrepancy between observed overvoltages during accidental faults and those obtained during staged tests has been noted in some cases. I would like to ask the authors if they have an explanation for this discrepancy.

Routine observations have shown that faults in enclosed insulation such as cable failures or bushing failures may lead to extinction and restriking of the arc at fundamental frequency. Overvoltages for this type of fault have been higher than for flashovers in air. I wonder if this type of fault has been observed by the authors or is the fault current too large to allow extinction of arcs initiated in the cables.

In regard to fault resistance, the joint subcommittee has co-operated with certain power companies in observing, by means of oscillographs, neutral currents during line-to-ground faults. By correlating these currents with particular fault locations, calculations have been made to determine the fault resistance necessary to yield estimates of neutral current equal to observed values. Most of these data have been obtained on overhead lines and very little data on all-cable systems. While one would expect the fault resistance to be low for cable failures, I should like to ask the authors if their observations have indicated any data on fault resistance.

H. J. Plumley: Concordia and Peterson have brought up the question of the possibility of differences in the peak transient overvoltages at various points in one 12-kv zone. Such differences undoubtedly exist but it is our opinion that they are not large. On figure 1 it will be noticed that in one zone there are two widely separated spark-gap installations. The settings are maintained at the same value at both places. During the sphere-gap period 1932–38, nine line failures initiated transients capable of causing gap operations. In seven of these cases surges were recorded at both installations.

Mr. Dunham inquires about a possible explanation of the discrepancy between observed overvoltages during accidental faults and those obtained during staged tests, the latter not being equal to some of the former in magnitude. We feel that there was no discrepancy in our tests. The production of overvoltages was not the primary objective; hence no effort was made to time the application of the faults to obtain maximum surges. Since only five per cent of all service failures will cause surges exceeding $3N$ (see figure 6 of the paper), the 15 random test shots were insufficient to ensure the production of a maximum surge. We think it likely that maximum surges could be produced almost every shot, if desired, by proper location and timing of the artificial fault.

With reference to intermittent arcing in enclosed insulation, automatic oscillograph records obtained on the Chicago 12-kv system show this phenomenon to be very rare in the case of cable faults but rather common in the case of faults in cable joints. The intermittency is usually of longer period than fundamental frequency, restriking once or twice a second being common. In regard to Mr. Dunham's last question, no effort has ever been made to determine the resistance of a fault on the Chicago 12-kv system. The fault resistance in a 12-kv lead-sheathed cable is probably so low that its exact evaluation would be very difficult, because the resistance of the system neutral resistor is continually changing during a fault due to its resistance-temperature characteristic.

Report on Apparatus Bushings

Discussion of paper 41-76 by the AIEE joint committee on bushings, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) page 266.

J. R. North (The Commonwealth and Southern Corporation, Jackson, Mich.): This report represents the results of a concerted detailed analysis of the electrical characteristics of present-day bushings and their operating performance requirements. The recommendations of the committee are based on providing a reasonable margin of insulation strength above the voltages which may be expected in service, including both low-frequency surges and lightning surges as limited by modern protective devices. A brief discussion of some of the values given in table I may be of interest.

All values of test voltages are expressed in terms of "withstand voltages" rather than as flashover voltages and there are no negative tolerance allowances. The "insulation classification" voltages may be considered as general indices, but bushings may be used for apparatus of a higher voltage rating when adequate for a particular application.

For outdoor bushings the low-frequency wet-test voltages were first determined and after a consideration of surge voltages which might be experienced in practice, these were taken as equal to approximately $3.2E_n+15$ kv. Similarly for the low-frequency dry tests, the values were chosen as equal to approximately $4E_n+15$ kv to provide a suitable manufacturing ratio between dry and wet values and an operating margin above the wet-test values. The outdoor bushings for small apparatus, insulation classifications 15 kv and below, were taken the same as the values for large apparatus but one step lower.

The indoor bushings were considered to require only dry low-frequency tests and the numerical values were taken the same as for the wet tests for large apparatus outdoor bushings.

The impulse test values for both indoor and outdoor bushings were selected from the series of standard basic insulation levels.

It is to be hoped that these bushing standards will receive immediate general acceptance throughout the industry, both by manufacturers and users alike, as this will very definitely result in economic savings of considerable value through the simplification of design and application schedules.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): The question may well be asked: "How do the proposed withstand values compare with the flashover values for bushings which are now being supplied for standard equipment?" To throw some light on this subject, the committee collected considerable authentic data on the average flashover of bushings in the voltage classification of 8.7 up to and including 230 kv in the course of their study on the bushing insulation problem. These data, together with the committee's recommended withstand values (impulse, wet, and dry withstand) for outdoor bushings, are shown graphically in figure 1.

It will be noted that there has been considerable variation in the average flashover of bushings in the general range from the 15-kv class up to and including the 69-kv class. It will also be noted that the withstand values proposed by the committee are in practically all cases slightly less than the average flashover values reported. This, of course, is to be expected and is necessary to put the values on a withstand basis. A study of these data, however, seems to indicate that the values proposed by the committee are comparable to the general average of bushings which have been supplied to the industry in the past. It is true that some users of equipment specify bushings in a class higher than the nominal classification of equipment. It therefore follows that the average flashover values given in figure 1 do not necessarily mean that these values represent present-day operating practice; on the contrary, they represent present-day manufacturers' rating.

The manufacturers' practice in supplying equipment, the users' practice in its application, and fundamental overvoltages appearing on systems, all have been studied and evaluated in arriving at the committee's recommended values as shown in table I.

In presenting this report, it is particularly gratifying to find that the committee has set up proposed standard values for bushing insulation characteristics without specifically assigning these bushings to any particular piece of equipment. Footnote *a* of the table clearly indicates that the bushings to be applied having the recommended electrical characteristics depend upon the particular application of the bushings to apparatus. From this it also follows that the particular bushing selected for any piece of apparatus may also be influenced by the application of the apparatus itself.

In our own company in the past we have made frequent applications of bushings on large equipment of relatively major importance where so-called oversized bushings have been employed in medium and low-voltage insulation classes. We are particularly desirous in low-voltage class bushings on major equipment of maintaining suitable, mechanical clearances which in turn usually means a bushing with higher electric characteristics. In the higher voltage classes of equipment, we have, however, during recent years been using 115-kv class bushings on 138-kv transformers and experiencing no insulation troubles from this practice.

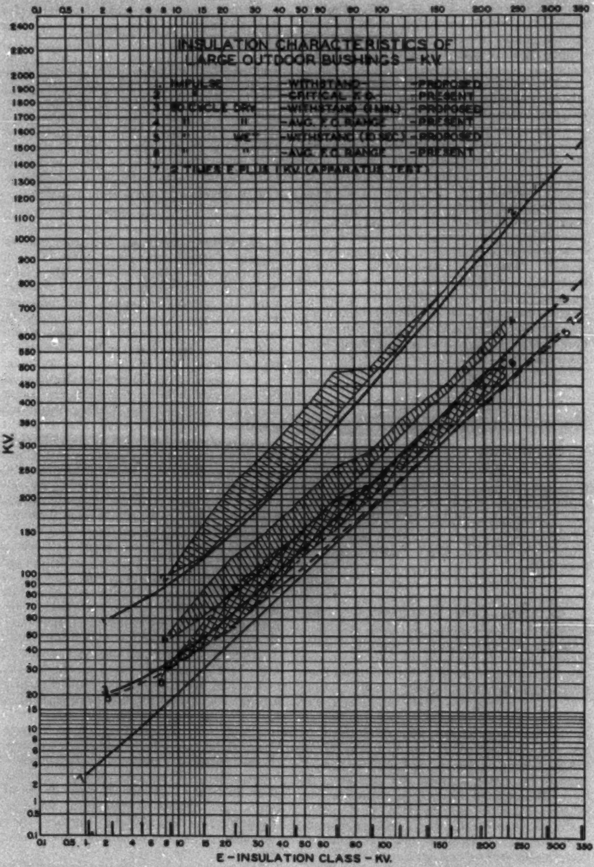

Figure 1

It therefore follows that the insulation classification given in the first column of the table does not in any way require that bushings of a given class must be used on equipment carrying the same system voltage rating. This is a most important point to keep in mind when assigning standard bushings in table I to various classes of equipment. It is hoped that this point will not be lost sight of by the various committees charged with the selection of bushings for different pieces of equipment in the various circuit voltage classifications.

High-Voltage Bushings Designed to Meet Modern Service

Discussion and authors' closure of paper 41-66 by T. F. Brandt and H. L. Rorden, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 255–60.

M. C. Westrate (The Commonwealth and Southern Corporation, Jackson, Mich): This paper has been reviewed with a great deal of interest. The information presented in this paper is both educational and practical.

Of particular interest is the change in the volt-time characteristic of the new type of bushing which, as the authors mention, approaches that of a sphere gap rather than a rod gap. This also makes the bushing volt-time characteristic approach that of transformer insulation and should lend itself to a better co-ordinated over-all design of transformers. The question, then, is what determines the rating of the bushing inasmuch as both the 60-cycle and impulse full-wave flashovers have been materially increased for a given size of bushing.

This change of the bushing volt-time characteristics also presents another problem in that they are not inherently co-ordinated with rod gaps and, therefore, would not be protected by them unless set for considerably lower full-wave impulse flashover, such as now encountered with protection of transformer windings.

A rather interesting observation is made from table I in that for the specified level of radio interference the corona and radio interference points occur at the same voltage with the new type of design whereas older types showed a decided difference.

F. O. Wollaston (Commonwealth Edison Company, Chicago, Ill.): Mechanical troubles with high-voltage bushings have been much more prevalent than the manufacturers would have us believe. For example, more than 70 bushings were repaired or replaced in Chicago because of leaks in the last three years. In some other cases, moisture entered bushings of the oil-filled, free-breathing type, necessitating maintenance of the oil.

Three main requirements for bushings are evident which have not been adequately taken care of in any designs for which service experience has been had in Chicago:

1. Electrical contacts: Concealed contacts should be positive, not depending on wiping pressures, screw-thread pressures, or spring pressures.
2. Entrance of moisture should be made impossible; that is, a completely closed system is essential. There is no objection to including a closed auxiliary oil-reservoir as part of such a system.
3. Internal pressure in the bushing should be controlled and held to a small range of variation, preferably not going below atmospheric.

It has been found in Chicago that gaskets are prone to give way in compound-filled bushings, which are typically subject to high ranges of internal pressure. In oil-filled breather-type bushings it has been found that moisture eventually collects in the bushing, sometimes in considerable quantity. For completely-sealed bushings, it is regarded as essential that the top seal be simple and positive, preferably a soldered seal. It also seems very desirable to keep the internal pressure range low in such bushings, to reduce the duty on gasketed joints to a trouble-free level.

Referring to figure 11, it would be preferable to have a soldered instead of bolted seal on the cover plate of the oil reservoir and to have the magnetic gauge screwed into the side of the reservoir and soldered.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): An eminent scientist is reported to have said, in effect: "You cannot begin to talk about a thing until you can define it." If the authors had believed this, and accepted the definition of a bushing given by the AIEE sectional committee on electrical definitions *C*-42, they probably would not have presented this paper. The definition referred to reads in principal part: "A bushing is a lining for a hole."

They are, however, to be complimented on visualizing a bushing from a more practical viewpoint, and have discussed modern bushing design accordingly. Two design considerations they have mentioned deserve comment. *First:* That the electrical characteristics should be stable in so far as they affect operating performance. And *second:* A design which is subject to change under operating conditions is undesirable.

The first implies that the materials used in the bushing should be so chosen that effects injurious to any part will not be produced by some other part, such as the mixing of oil with compound, dissolving of varnishes in insulating liquids, and deterioration of sealing gaskets because they are in contact with liquids, or in some cases because they are not in contact with saturating liquids. This brings up the second consideration that changes in the electrical characteristics under operating conditions are undesirable.

As the result of some ten years of systematic and continuous field power-factor testing of thousands of bushings on oil circuit breakers and transformers, we have been convinced that one of the major troubles experienced with bushings in service is the presence in the insulation of moisture usually admitted through faulty gaskets. Various methods have been tried, with more or less success, in an attempt to perfect this gasket sealing problem, such as the use of better gasket material, insulating liquids heavier than water, multiple gasket seals, and even arrangements to restrict the circulation of moisture when it once enters the bushing.

Recognizing, however, that a bushing like any other piece of equipment, must be maintained, and may occasionally require gasket replacement, means should be provided to readily make this change. Concealed gaskets placed behind inaccessible barriers of cement are sources of potential trouble and grief. If found defective before bushing failure occurs, it is often necessary to scrap the bushing, or incur an excessive labor cost in machining out the cement and replacing such gaskets. The type of gasket design described by the authors where constant pressure is maintained and replacement easily made, is a distinct improvement which it is hoped will be eventually extended to bushing designs in all voltage classes.

I would like to ask the authors whether or not the resistance grading obtained by the conducting glaze is going to give a bushing with a stabilized power factor over a period of time, and also whether commercial bushings of this type have practically the same or widely different power factors.

L. Wetherill (General Electric Company, Pittsfield, Mass.): There is a striking relationship between figures 6 and 9 of the paper. In each case the flashover strength is increased by a conducting surface of smooth contour located so as to reduce the voltage gradient in air at the region where flashover would start. Creation of the conducting shielding surface under the lowest petticoat as shown in figure 6 is a natural phenomenon resulting from the application of overvoltage. It is not an uncommon occurrence in dielectric structures that the initial discharge under increasing voltage is such as to increase the dielectric strength and such as to suggest the nature of a modification in design which will give increased strength.

Influenced by the observation that a porcelain petticoat will serve to limit the progress of streamers created by overvoltage and retard the development of a complete flashover, practically all large bushings are now provided with a porcelain petticoat located fairly close to the ground metal of the support flange of the bushing, in order to limit such streamers as much as possible. The older design in which the lowest petticoat is elevated a considerable distance above the ground metal is now rarely manufactured.

Frequently when a useful natural phenomenon is noted, it is possible to improve upon it by proper designing. The shielding shown in figure 9, which utilizes a conducting surface of smooth contour located inside of the bushing shell, offers greater effectiveness in preventing flashover at moderate overvoltage.

Metallic shields similar in location and configuration have been used for this purpose in some types of oil-filled bushings for many years. The original adoption of this construction was for the purpose of suppressing corona and increasing the flashover voltage. A secondary result which has since become important is the almost complete suppression of radio frequency voltage.

The statement is made by the authors that most gasket materials kept under constant pressure between mating surfaces remain oil-tight indefinitely. This is in accord with usual experience. The principal gaskets in oil-filled bushings are kept tight by heavy spring washers mounted on the clamping bolts. For example, the large gasket on a 138-kv bushing is subjected to a spring follow-up force of about 10,000 pounds. Due to the local clamping structure, all of the resilience of the extra-heavy spring washers is available for taking up any set that may occur in the gasket material. None of the resilience need be reserved for thermal expansion of the conductor which in very large bushings may amount to more than $^1/_8$ inch.

There are conditions in which follow-up pressure is not needed. There are a number of gasket materials available which are readily deformed, but are volumetrically incompressible. Many gaskets of this nature have been successfully used in constructions providing complete enclosure of the gasket on all surfaces. Such a gasket cannot flow or take a permanent set. Over 100,000 gaskets of this type have been used in the last ten years with entirely satisfactory results. There have been no cases of leakage reported on volumetrically controlled gaskets of this construction used on liquid-filled bushings when the gaskets were properly assembled in the bushings.

The volumetrically incompressible gasket material is also used against flat surfaces with only the edges exposed. In such a case, spring follow-up pressure is provided to compensate for any slight flow which may occur. Altogether there are some half million gaskets of this material in service and there have been no cases of leakage reported which reflect upon the property of the gasket material.

Flat gaskets provided with spring follow-up pressure have been very satisfactory against oil pressure. However, there is considerable experience indicating that even with spring follow-up pressure, the usual type of composition cork gasket, while satisfactory against oil pressure, is not an adequate seal against gas pressure in a small hermetically sealed structure such as a bushing. For sealing against gas pressure, a less porous gasket material is essential, as indicated by years' experience with manufacture of hermetically sealed liquid-filled bushings.

T. F. Brandt and H. L. Rorden: It may be inferred from the various discussions that the question of greatest concern in the performance of high-voltage bushings in general is that of leakage. A perfect performance record is, of course, difficult to achieve, but bushings of the compression type, in which the gaskets have been kept under constant pressure at all times have an excellent service record. Reaction of the industry to this feature has been very encouraging and we are further gratified at Messrs. Wetherill and Gross' concurrence in this opinion.

In the type of bushing described in the paper, all gaskets which come in contact with the bushing oil are maintained under constant spring pressure. This usually involves three or more gasketed joints and experience has proved these joints to be one of the lesser leakage offenders. All other joints which may involve oil leakage are hermetically sealed.

We believe Mr. Wetherill has confused hermetic sealing with bushings that are oil and air tight. A hermetically sealed bushing would indicate that all mating parts are sealed by fusion and there are no gasketed joints. Obviously, bushing gaskets may be exposed to the atmosphere or other gas pressures. Bushings are then not hermetically sealed and the gaskets are subjected to a difference of gas pressure if the pressure within the bushing differs from that of the atmosphere. The usual composition cork gasket properly treated is an excellent seal against both oil and gas pressure.

While hermetic sealing of the bushing reservoir against possible breathing as suggested by Mr. Wollaston is undoubtedly very satisfactory, we believe the desired result can also be accomplished with properly made gasket seals. In general, bushings with solder-sealed reservoirs still contain gasket joints elsewhere, which are equally vulnerable to his objection. Also we think that gaskets in general should not be condemned based on their performance in older design compound-filled bushings. Present bushings of the type described otherwise satisfy Mr. Wollaston's opinion that bushings should not breathe and the internal pressure range should be restricted.

Mr. Wollaston leaves us in some doubt regarding his statement that electrical contacts have not been adequately taken care of in any bushing designs involved in his experience. It is obviously necessary in bushings of high-current ratings to exercise considerable care with the electric contacts, but in bushings of the most common amperage, wiping, screw thread, and spring pressures have been in common use for many years and have proved generally satisfactory.

We are glad to agree with Mr. Wetherill that designs are influenced by observation of natural phenomena. Undoubtedly by far the greatest part of our information is obtained empirically rather than by rational analysis. The general principle of the shielding referred to by Mr. Wetherill is common knowledge and has been in use for many years. In extending this principle by the application of conduction glazes, we have leaned heavily upon the results of tests rather than mathematical analyses. Factors of major importance in the potential distribution could not be included in the calculation of stresses and so these results could not be given full confidence.

The method of internal shielding which we have described eliminates the tendency to overstress the field at the flange external to the bushing as discussed by Mr. Wetherill. With this internal shielding, bushings having high petticoats have some points in their favor. The fact that they are now rarely manufactured is due to manufacturing rather than electrical stress reasons.

Mr. Westrate raises some interesting questions relative to system co-ordination. The volt-time characteristics illustrated for the new design bushings are between the extremes of the rod gap and the sphere gap, and this raises the critical impulse and 60-cycle flashovers for a given size of bushing. To compensate for this it has been necessary to revise the bushing sizes so that their flashover voltages are consistent with their ratings, although co-ordination is not necessarily expected to be obtained with the bushing, as such, a factor in the flashover levels.

The change in the bushing volt-time characteristics should be an advantage, since the ultimate end is protection of the transformer. These bushing curves more nearly parallel those of transformer insulation, and with an appropriate margin between them should offer ideal co-ordination.

Mr. Westrate's reference to radio levels is of interest since bushings with adequate internal shielding in general have unusually good radio interference characteristics.

In reply to Mr. Gross' question regarding power factor, we wish to state that the power factor of otherwise identical bushings varies between the limits of accuracy obtainable in vitrifying these glazes to within a narrow range of conductivity, which seems difficult to achieve at present. The glaze used on bushings of the type described has widely different characteristics from that used in the treatment of insulators against radio interference. The variation in resistance results in somewhat different power factors, but the power factor of each bushing is stable. The permanence of this glaze has been well established by years of service in other forms of insulators. This power factor is due to the surface conductivity on the dielectric material and is not conductivity through the insulation barriers. Therefore, it is not indicative of the condition of the dielectric material.

Secondary Networks to Serve Industrial Plants

Discussion and authors' closure of paper 41-48 by C. A. Powel and H. G. Barnett, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section) pages 154–6.

D. L. Beeman (General Electric Company, Schenectady, N. Y.): The merits of the secondary network system as outlined by the authors should be given full consideration when considering distribution systems for factories in which reliability of service is of particular importance. The basic idea presented in the paper, that is, using high-voltage distribution to small step-down stations located throughout the buildings affords, in many cases, substantial savings in the investment in the electrical system.

Network distribution systems have been used in factories for several years. Noninflammable liquid-filled transformers have been used in such installations and have reduced the over-all costs because they can be located in the buildings at the load centers, thereby saving expensive long runs of heavy copper that may be required if the transformers had to be located away from the load center outside the buildings.

The comparison of initial costs of the radial and network systems in the authors' paper is based on a network system using high-voltage distribution to load centers, and a radial system using low-voltage distribution throughout the plant. They have selected a large enough installation to show that distribution at high voltage, even with the duplication of equipment required for the network, is less expensive than the low-voltage radial distribution system.

It seems reasonable that we should also compare the network system with a radial system using high-voltage feeders supplying small distribution units located at load centers throughout the factory.

Such a comparison will verify the basic advantages of the network given in the authors' paper, i.e., the network is the lowest cost scheme to provide the greatest service reliability. If, however, service reliability is not of paramount importance, this comparison will show that the initial investment may be reduced by using the radial system with high-voltage distribution to load centers. This is because such a radial system requires less equipment as outlined in the following:

1. A lower investment may be required in secondary cable because of the absence of secondary ties.

2. When all transformer secondaries are banked, as they are in a network system, short-circuit currents are increased over what they would be if the same size transformers were not banked. That necessitates larger branch feeder air circuit breakers for the network system or conversely smaller ones in the radial system.

3. Although the authors show limiters or fuses being used in the secondary ties of the network, it is questionable whether or not some form of disconnecting means would be required in the ties to permit greater flexibility in operation: for example, to permit de-energizing a certain area readily in case of an emergency. Such disconnecting means are not required in the radial system.

There are two basic methods of factory distribution; one at utilization voltage, and the other at high voltage. The high-voltage method is applicable to either the network system as outlined by the authors, or at a radial system using distribution stations located through the factory at load centers.

P. W. Crosby (Philadelphia Electric Company, Philadelphia, Pa.): The paper presented by Messrs. Powel and Barnett brings out a very interesting point; that is, the same principle applied so successfully to the distribution systems in high-load density areas of large cities is likewise applicable to distribution systems for industrial plants. That principle is to provide an interconnected distribution system with a protective scheme so designed that in the event of a fault, only the faulty part of the system will be isolated and this, due to the interconnections, without interruption of service to any part of the load.

Two types of low-voltage a-c networks, embodying two different methods of the application of this principle, have successfully met the exacting requirements in high-load density city areas where service continuity is so important. It is therefore axiomatic that these systems should prove advantageous in providing highly reliable service in industrial plants.

The authors have described in their paper only one of these two types of a-c networks; the one in which two or more *radial* primary feeders supply a low-voltage grid through step-down transformers and automatic network protectors. In this system the entire primary feeder and all of its associated transformers are controlled as a unit in the protective scheme. The entire feeder and all of its associated transformers are removed from service in the event of a primary feeder fault.

The other type of a-c network system with several years of successful operation in high-load density city areas is the one in which sectionalized *loop* primary feeders are used. This system has several features which make it applicable for distribution in industrial plants.

The sectionalized loop feeder method of supply to low-voltage networks is, in many respects, fundamentally different from the radial feeder method. The loop feeders are sectionalized by means of automatic primary circuit breakers. The protective scheme consists of a simple direct acting pilot wire system which trips the breakers at each end of the faulty section of feeder. Only one section of primary feeder and its one transformer bank are isolated in the event of a primary feeder or transformer failure. All of the other transformers connected to the feeder remain in service, being supplied from the two parts of the loop feeder which have been separated by isolation of the faulted section. The faulted feeder section and its transformer are disconnected from the low-voltage grid by simple copper link fuses in the secondary leads of the transformer. Since only one transformer is removed from service, it is not necessary to use automatic network protectors. Also due to this feature, the occurrence of a fault causes a minimum of disturbance to the remainder of the system and makes possible a greater utilization of installed transformer capacity.

The sectionalized loop feeder system is particularly well adapted to the supply of both networked and nonnetworked loads from the same feeder, due to the feeder section method of control. This means that large primary voltage motors, frequently encountered in industrial plants, could be supplied from a section of the same feeder as used to supply low-voltage network load. Such nonnetworked loads would be subjected to interruption only in the event of a fault in their own section of feeder.

For systems having extremely high fault duty, control schemes have recently been developed whereby breakers of relatively low interrupting capacity may be used to sectionalize the primary loop feeders. A fusing scheme has also been developed for assuring the blowing of transformer fuses on networks of low available fault current and the selective blowing of fuses on spot networks having only two transformer banks.

It may be interesting to note that a sectionalized primary loop feeder system is now being installed in a large midwest industrial plant. It is believed that thorough consideration should be given to both types of systems to determine the one most suitable for any particular plant.

A. G. Darling (General Electric Company, Schenectady, N. Y.): A considerable number of network systems have been installed in industrial plants over a period of years, some serving power and some serving lighting uses and all seem to satisfy their owners. One large manufacturing plant has in operation over 50 transformers of 500 kva each, supplying several 120/208 lighting networks, and plans to extend these networks as occasion demands. Another plant has connected about six 1,500- to 2,000-kva transformers on a 575-volt power supply ring bus interconnecting several buildings and has plans to extend the network to include ultimately 12 2,000-kva transformers. From each transformer station, radial feeders supply the loads in these two instances, no loads being taken from the tie circuits between transformers.

Still another variety of network utilizes the tie circuits between transformers as a means of supplying the loads through tap-off circuit breakers to local busses from which radial breaker-protected feeders are connected. The transformers are so located as to maintain the voltage on the ring bus at a level to allow for the very small drop in the short radial feeders. Since the ring bus is geographically placed around the building interior at a distance from all outside walls to give short runs from the bus to the walls or to the center of the building, no load need be more than one-fourth of the building width away from the bus. This plan has the distinct advantage of making the most expensive part of the installation the most permanent while the less permanent feeder runs become the less expensive part of the installation. It retains the advantage of other networks in that the transformer capacity may be increased, decreased, or moved to another point on the ring bus. Two kinds of equipment are available for busses—the rigid metal enclosed structural shape conductors or insulated, nonmagnetically metal sheathed cable. Both types can be tapped at any desired points, the bare conductor rigid bus, metal enclosed, being the more accessible of the two types, but the cable being less expensive, giving better voltage regulation and being more susceptible to adding or taking away parallel cables as the loads change.

The authors point to many advantages of the low-voltage network which supplies loads from transformer busses, over the low-voltage radial system of distribution. They mention reliability, good voltage regulation, high economy, and flexibility in adding or taking out transformer capacity and transformer busses from which radial loads are supplied. These advantages likewise apply to the ring bus from which loads are fed but which gives the added advantage of ability to supply radial loads from any point on the ring with minimum radial feed distance and minimum disturbance to transformers and busses. Incidentally a straight line bus may be used if the occasion does not demand a ring bus. Certain experience with layouts of radial and network systems indicates that the several important advantages of the network including automatic tie breakers can be secured for about ten per cent more than the cost of the radial system.

No doubt many designers are giving special thought to reliability in these days. Alternate sources of supply, segregation of loads, quick replacement of unusable equipment as well as flexibility in utilization became relatively more important under uncertain circumstances. Certain forms of network systems offer these advantages and all forms give good regulation and alternate sources of supply.

William W. Edson (Boston Edison Company, Boston, Mass.): A similar application of a secondary network to industrial plants is the supply for turbine and boiler auxiliaries. In both cases consideration of some of the problems which have arisen in the operation of metropolitan networks should be given.

If two transformers are too close together, especially if they are fed by separate high tension feeders, they may not divide the load equally. At light loads one transformer may pump, thereby increasing the wear on the secondary protector. Extreme cases may require balancing transformers to equalize the load.

Large regenerative loads such as elevators might open the protector unless special desensitizing relays are added.

Double-throw disconnects are shown to transfer from a dead high tension feeder to one alive. In order to get back to the original schedule of transformers and feeders it may be necessary to have an interruption of service. Opening the secondary protector removes the necessity of the high tension switch opening load current but the switch would still have to break magnetizing current which is often hazardous. In fact metropolitan units are provided with electrical interlocks to prevent breaking magnetizing currents.

The combination air-cooled transformer and switching equipment offers many advantages but due to the high operating temperatures permitted the design should be such as to encourage frequent cleaning. Access parts, etc., may need to be interlocked with the high tension disconnect. Suitable barriers should be provided between the transformer and the high tension disconnect and the protector.

Several conductors per phase in the secondary bus runs permit use of sectionalizing limiters and is more economical in the use of copper than one large wire, however, the total reactance is less which might be a disadvantage. A fault or starting a large motor will cause a serious voltage dip throughout the plant if the impedances in the network are too small, thus other motors or controls may drop out.

Essential motors might require a throwover switch to another part of the system to prevent an outage if its circuit or part of the net is segregated by fuses.

Special connections will be required to isolate a building or part of a plant out of use or in case of fire.

The following modification of the usual secondary network is offered for consideration:

The secondary network units are located at the various floors or load centers with motors and associated circuits connected to the unit busses somewhat like the usual radial system. Each bus has a reactor which connects to a common reactor bus thus tying the units together.

A fault on one section will have less effect on the rest of the system. The short-circuit duty required for the limiters, circuit breakers, and motor starters is much less. Any section can be shut down or isolated from the rest of the system by opening the reactor tie. In case of a transformer or high tension feeder fault, service is maintained from the remaining transformers through the reactor bus. Additions or changes to any bus section can be made easier. The reactors required are small and in some cases may be eliminated if the impedance of the reactor bus is high. The reactor bus may serve as a duplicate source for essential motors. It may also be used as a starting bus for exceptionally large motors.

A. P. Schnyder (George F. Hardy, Consulting Engineer, New York, N. Y.): The authors express awareness that industrial plants as to system of power distribution defy too broad a generalization. The electrical tools vary in kind, type, and size from group to group to such an extent as to render the task of selecting an all inclusively appropriate pattern even for distribution most difficult.

Commenting on the paper as to possible adaptation of networks in paper mills, for reasons explained in the following, there seems justified doubt that they offer advantages over the present practice of radial feeder distributions.

1. Load densities per 1,000 square feet ground area in mill and yard are extremely small in the wood yard, reach 8 kw in shops, 700 kw in stock preparing room, and several fold the latter amount in grinder rooms.

Feeders supply singly motors driving grinders or paper machine motor generator set varying in size from 1,000–4,000 horsepower, in groups motors between 50 and 500 horsepower in a particular department, all above at 2,200 volts. These larger motors represent roughly two-thirds of total mill load.

2. Mill managements are cost minded and require accurate departmental power load readings which can be readily made available with radial feeders.

3. A mill is constituted by a chain of process equipments from wood yard to shipping platform. A number of equipments are single links and are driven by individual motors. Mechanical troubles and process stock difficulties are incomparably more bothersome than electrical troubles. The latter again originate predominantly in the motors and controls rather than in the distribution system. The greater reliability of network at the comparatively higher cost of installation would merely increase the safety factor which in the radial feeder system is already a very conservative one.

4. Last but not least is the human element. The radial system is more direct and easier understood by the average operator. The lot of a mill electrician is not uniformly enviable. He requires absolute familiarity with his system which is naturally more definitely assured the simpler such system is. To use a somewhat disrespectful term the less "gadgets" the better.

C. A. Powel and H. G. Barnett: The discussers have all added useful thoughts to the subject matter of the paper. The general tenor of the questions raised deals with the economics of the situation rather than the engineering.

It is true that if reliability is sacrificed certain radial type systems may show a saving in cost over network systems. However, industry today is so dependent on electricity and the general understanding by factory operators of electric supply problems is so much higher than it was a few years ago, that we should not be satisfied with anything less than maximum reliability, if this can be obtained without unreasonable increase in cost. A radial system designed to provide reliability approaching that of the network system will certainly cost more than the network scheme.

The loop system described by Mr. Crosby is applicable to factory supply, but we question if it would show any saving over the conventional network system, because of the necessary primary breakers and pilot wire control.

Mr. Edson suggests the necessity of having to interrupt service in order to get back to the original schedule of transformers and feeders after a feeder disturbance. The transfer of a transformer from one feeder to another can always be done without interruption of service, the selector switch being designed to break magnetizing current.

The loss of motors due to trouble in the supply can only originate with trouble in the junction boxes to which they are connected. The probability of loss of an essential motor due to this contingency is no greater than that due to trouble in the motor or its control equipment. Therefore, essential motors should be installed in duplicate and supplied from neighboring junction boxes rather than from the same junction box.

Enclosed Bus-Bar Electrical Distribution Systems for Industrial Plants

Discussion and author's closure of paper 41-64 by E. T. Carlson, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 297–302.

Herbert B. Dwight (Massachusetts Institute of Technology, Cambridge, Mass.): The account of the development of enclosed bus-bar systems given by Mr. Carlson is interesting, as is also the summary of the calculations needed in their design.

The reactance drop of a system of rectangular conductors connected $ABCABC\ldots\ldots\ldots$ as in figure 5 can be calculated by methods available at present, if the currents are known.

If ammeter readings show that for the arrangement of figure 5 the currents in all the conductors are practically equal in magnitude, which is to be expected in ordinary cases, then currents of phases A, B, and C may be taken to be 120 degrees apart in phase. Since the vector sum of all the currents is zero, I_a may be put equal to $-I_b-I_c-I_d\ldots$ where the sub letters represent the different conductors (not the phases). Then the method described by the writer in example II of the paper "Reactance Values for Rectangular Conductors" (reference 9) can be followed, and the drop in any conductor can be expressed in terms of the sum of a number of reactance drops in two-conductor, single-phase circuits. For this the curves of reference 9 will be found accurate and convenient.

An alternative method is to find the drop in any conductor by computing self-inductances and mutual inductances, counting flux up to a certain large distance u, and using self and mutual geometric mean distances as given for rectangular conductors by F. W. Grover in *Proceedings* Institute of Radio Engineers, volume 17, part 2, 1929, pages 2056–7, mentioned in Mr. Carlson's paper, following equation 6.

Thus,

$$L=2\log_n\frac{u}{R}\text{ abhenries per centimeter}$$

and

$$M=2\log_n\frac{u}{D}\text{ abhenries per centimeter}$$

The quantity u will cancel out, in the complete sum. See the first part of example II, reference 9.

The determination of current capacity and temperature rise of enclosed systems such as figure 5 will probably require full-load tests for almost every different size, in the same way that temperature tests are needed for transformers and rotating machines.

O. R. Schurig (General Electric Company, Schenectady, N. Y.): In his paper on "Enclosed Bus-Bar Electrical Distribution Systems for Industrial Plants," Mr. Carlson points out the desirability of having further knowledge relative to a-c–d-c resistance ratio and reactance applicable to commercial bus structures, particularly for closely spaced conductors as employed in commercial busways. The author has also indicated some of the difficulties connected with the analytical method of approach to the problem, the most important unknown factor being the distribution of current in the conductors themselves as determined by skin effect, proximity effect, and circulating currents in the metallic housing surrounding the bars.

In view of these difficulties and in order to obtain practical data on a-c–d-c resistance ratio, and on reactance as well as on impedance unbalance for typical busway assemblies, a series of tests was made at Schenectady.

The busway structures tested included those described in table I. This table also shows the phase current used and the following test data:

In column 6—the rms line-to-line drop V_{AC} measured for 30 feet of busway, across phases AC.

In column 7—the measured three-phase loss W for 30 feet of busway by two-wattmeter method.

In column 8—the impedance per phase to neutral in ohms per thousand feet (derived from V_{AC}) for a going and return circuit having a conductor spacing of 5.25 inches. The values were obtained from the relation:

$$Z=\frac{1{,}000V_{AC}}{30\times 1.73\times I}$$

where I is the line current from column 5. This relation holds for balanced line currents only.

In column 9—the average effective resistance per phase in ohms per 1,000 feet derived from W by the following relation:

$$R'=\frac{1{,}000W}{90I^2}$$

In column 10—the reactance per phase to neutral in ohms per 1,000 feet (derived from Z_{AC} and R') for a going and return circuit having a conductor spacing of 5.25 inches.

In column 11—the calculated value of X_{AC} determined by conventional method neglecting skin effect and circulating currents.

In column 12—d-c resistance.

In column 13—average a-c–d-c resistance ratio derived from columns 9 and 12.

Some of the significant points indicated by the results are the following:

1. The average a-c–d-c resistance ratio for the construction with one 4 by $^1/_4$-inch copper bar per phase at 60 cycles is of the order of 1.5 (see item *a*). This is materially in excess of the value of the isolated-bar skin effect resistance ratio, which is of the order of 1.12 (see Mr. Carlson's references 10 and 15). Obviously a substantial resistance increase due to narrow spacing and due to the metallic enclosure would be expected.

2. For the two-bar-per-phase construction with 4 by $^1/_4$-inch bars, the over-all a-c–d-c resistance ratio was found to be within the range from 1.75 to 1.83 (see item *b*). An isolated two-bar conductor with 4 by $^1/_4$-inch copper bars in the absence of a metallic housing, would have a 60-cycle–d-c resistance ratio of roughly 1.3, not shown in the table.

	2 bars $4x^1/_4$	6	A B C A B C Transposed	$^1/_4$	3,200	2.10	4,138	0.0126	0.0045	0.0118		0.0027	1.97

*Not transposed.

3. The two-bar-per-phase construction with 3 by $^1/_4$-inch bars (see item *c*) had an a-c–d-c resistance ratio within the range from 1.65 to 1.7.

4. The six-pole busway assembly with two 4 by $^1/_4$-inch copper bars per pole was found to have an over-all a-c–d-c resistance ratio of 1.7, or slightly less than the corresponding three-pole busway.

5. The reactance values, by test, are also of interest in that they are somewhat lower than the values calculated by the conventional method, at least for the two-bar-per-pole arrangements. This would be accounted for by the current distribution resulting from skin effect and proximity effect.

6. The impedance unbalance for the untransposed arrangements, indicated by the ratio of maximum-to-minimum line-to-line voltage drops was of the order of 1.32 to 1.45 (not shown in the table). This is roughly in accordance with the ratio of the reactance for $5^1/_4$-inch spacing to that for $2^5/_8$-inch spacing.

E. T. Carlson: I wish to thank Professor H. B. Dwight and Dr. O. R. Schurig for their excellent discussions which have added to the fund of information available on the subject of "Enclosed Bus-Bar Distribution Feeders."

Professor H. B. Dwight has referred in his discussion to the paper "Reactance Values for Rectangular Conductors," which describes in detail the determination of the 60-cycle reactance of parallel strap conductors.

He points out the necessity of knowing the current division in a multiple conductor system in order to ascertain the reactance drop by calculation methods now available.

The parallel Professor Dwight has drawn between the methods of determining the temperature rise in other electrical equipment and bus bars is appropriate. Actual tests of each size and each configuration are necessary.

The empirical data given by Dr. O. R. Schurig is a most valuable contribution. For the bus-bar configurations shown under column 3, the reactance values of rectangular conductors can be calculated within an accuracy of ten per cent.

The ratio of a-c to d-c resistance indicates the result of proximity and skin effects in increasing the a-c resistance. Doctor Schurig's data show that on close conductor spacings where the currents in adjacent bars are flowing in opposite directions, the a-c resistance approaches the d-c resistance. (See also reference 15.)

This is a fortunate situation and has given encouragement to the manufacturers of busway systems in their efforts to produce acceptable designs having low reactance which in turn has meant facing the problem of placing bars on very close spacings.

Experience With Preventive Lightning Protection on Transmission Lines

Discussion and author's closure of paper 41-36 by S. K. Waldorf, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 249–54.

F. Von Voigtlander (The Commonwealth and Southern Corporation, Jackson, Mich.): The general conclusions reached by the author regarding distribution of current in tower members, the high degree of effectiveness of single ground wires on towers of vertical configuration, and the doubtful benefits of reducing tower footing resistances below seven ohms have been substantiated by the experiences of companies of the Commonwealth and Southern system.

Similarly, wide discrepancies have also been noted between measured surge voltages and those calculated from surge currents and footing resistances. For ground resistances obtained with the tower footings by themselves, with deep driven ground rods, or with counterpoises, experience consistently indicates that the surge resistances are considerably lower than resistances measured by conventional low-voltage methods. Recent investigations such as those reported by Bellaschi, further confirm the conclusion that surge resistances are lower than the low-voltage resistances. These results would give even lower ratios of tower potentials (based on *IR* drop) to flashover levels than those cited in table III of the paper and would tend to emphasize the importance of reactive components in calculations of surge impedances.

The magnitudes of tower footing resistances regarded as desirable have been developed by making them small compared to the surge impedances of the other components of the electric circuit involved. It is quite probable that with low tower footing resistances, the reactance factors are of greater relative importance than previously considered.

The writer would like to ask if any oscillographic data have been obtained which would indicate whether these apparent reactive components are functions of large surge currents, steep wave fronts, or some combination of both.

C. F. Wagner and **G. D. McCann** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper presents valuable information relating not only to the performance of actual lines but to the fundamental properties of strokes to transmission lines. Dr. Waldorf has allowed us to examine the large amount of data which he has obtained and from this examination several interesting facts have developed.

Upon breaking up the data into time of occurrence of the stroke, it was found that seasonal effects are important. Figure 1 shows that the stroke current (obtained by adding the current in all the towers thought to have been involved in the stroke) is much larger during the summer than during the spring or fall.

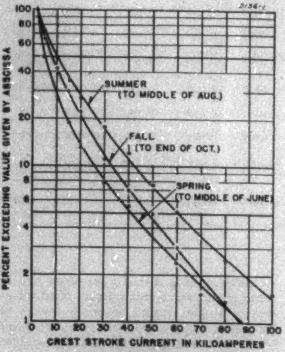

Figure 1. Effect of seasons on crest magnitude of stroke current as shown by Waldorf's data

In figure 2 are plotted distribution curves for both tower and stroke currents segregated into the two common ranges of span length used on the lines described. These curves indicate that a variance of span length of almost two to one has little effect upon the stroke current but, as might be expected, does influence the tower currents, that is, the longer the span the greater the concentration in a small number of towers. Also, the total stroke current curves show little variance between the different individual lines.

For the low range of tower footing resistances obtaining in these lines, very few being in excess of 25 ohms, the data indicate no effect upon either the stroke or tower currents.

A weighted mean of the number of strokes to the lines from table II gives a value of 120 strokes for 100 miles per year. This is the best datum of this nature available and when used in connection with per cent distribution curves permits of converting such curves into working curves of number of strokes per 100 miles per year as a function of the stroke current. In view of other data on this point which give a lower estimate, coupled with the fact that perhaps an appreciable proportion of Waldorf's current indications may be due to induction, a rounded figure of 100 appears reasonable. On this basis the data of both Waldorf and Lewis and Foust[4] have been plotted in figure 3. The dotted curve of Lewis and Foust was plotted directly from their data and the full line curve has been adjusted to correspond to the same minimum current as considered in the curve of Waldorf. Data of stroke currents rather than tower currents are valuable in that they may be used for estimating purposes on lines of different construction and should not vary with span length as do tower currents.

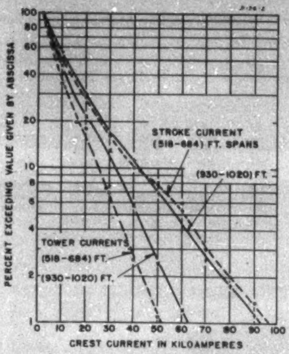

Figure 2. Effect of span length on tower and total stroke currents as shown by Waldorf's data

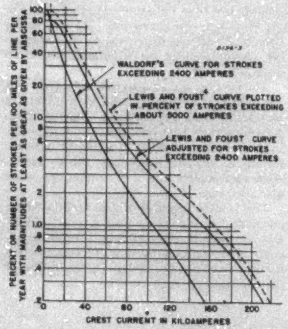

Figure 3. Probability curves of crest currents in lightning strokes to transmission lines

Based on 100 strokes to line per 100 miles of line per year

In view of the many variables involved in the shielding problem, it is gratifying that the results of operating experience agree as closely as they do to the results of investigations on laboratory models. The more optimistic results reported by Dr. Waldorf over that obtained by Wagner, McCann, and MacLane[6] may be due to the low pessimistic assumption of cloud height made by the latter.

While Dr. Waldorf recognized the uncertainty of his conclusions with regard to the possible effect of the inductive drop of the tower in producing insulator flashovers, it might be well to enumerate the important factors which enter into the problem. These are

1. Errors in total tower current arising from measurements of only one leg in the presence of unequal distribution between legs.
2. Contribution of cross braces to total tower current which may introduce correction factors of two or greater.
3. Seasonal variation of soil resistivity.
4. Momentary initially high impedance of footing resistance or counterpoise over the measured resistance.
5. Inductive drop or surge impedance of the tower.
6. Coupling between ground wire and conductor.

The first five factors may account for higher than calculated tower top potentials and the last item effectively decreases the potential across the insulator string below that of the tower top.

E. W. Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Waldorf's paper adds considerably to the fund of practical field data on lightning duty. We are particularly interested in the records of discharges through lightning arresters, and we hope that Mr. Waldorf will publish more complete data on his measurements, and more closely define his "small" currents. It is to be expected that the average currents through arresters will be less than the average currents discharged to a line, and that the discharge duty on arresters connected to lines with adequate ground wire protection will be less than on arresters connected to unshielded or poorly shielded lines. In a paper written several years ago, Mr. Opsahl[1] calculated that the usual current discharged through arresters would not exceed a few thousand amperes unless strokes occurred close to the arrester. Mr. Waldorf's comments regarding arrester records indicate that this is what he found, and field studies with which we have been associated show the same result. In fact, it has been recognized that complete over-all protection for apparatus can be more readily realized if the lightning arrester is assisted by shielding of some form. On highly insulated and improved lines not equipped with ground wires, the use of De-ion protector tubes ahead of the arresters has been recommended and used for this purpose. We have had an opportunity to measure discharge currents through an arrester by means of oscillograph and fulchronograph with and without tubes on the line, and have found the discharge currents through the arresters to be increased many fold when the tubes were disconnected.

It must be borne in mind that surges which discharge moderate currents through arresters would, if no arresters were present, produce sufficient voltage at the arrester

---

4, 6. See references 4 and 6 of paper.

location to endanger apparatus. For example, speaking in round figures, in the 69-kv class, 300 amperes through an arrester indicates the appearance of a surge voltage, if no arrester were present, of 350-kv the BIL for this voltage class. Mr. Waldorf has recorded currents of 2,600 amperes on shielded lines, if our interpretation of the data is correct.

Arresters were originally designed for, and standard tests were based on, discharge currents rather limited compared to present requirements. As time went on, and more data became available, it was recognized that high currents might occasionally occur. Arrester characteristics and capacities were improved to keep pace with the increased knowledge, and to take care not only of the usual cases but also of the infrequent ones.

The useful part that arresters play in the complete protection of stations and station equipment is well illustrated by Mr. Waldorf's comments regarding arrester discharges involving currents up to 2,600 amperes on shielded lines, and 7,400 amperes, a considerable current as arrester currents go, on unshielded lines.

G. D. Floyd (Hydro-Electric Power Commission of Ontario, Toronto, Canada): It is interesting to note (subsection VII) that the author has found that surge current times tower footing resistance may not be a measure of the potential at which flashover will occur. He suggests that there is a reactance drop present which increases the tower potential faster than would be indicated by the product of surge current and tower footing resistance. It is well known that there is a time factor in the strength of the insulation. There may be as great a ratio as two to one in the insulation strength of the insulator string, and this might account in great part for the fact that currents less than those required to produce flashover on the basis of current times tower footing resistance, actually did produce flashover.

Referring to subsection VIII of the paper defining the efficiency of protection, I believe this definition of efficiency could be improved. As it stands, it is likely to be misleading because even on a line where no special measures have been taken to prevent interruption, the efficiency as defined would be quite high. In order to show the benefit of special measures the datum should be higher. It does not seem reasonable to take the total number of strokes as a base when possibly 50 per cent of the total would not produce flashover in any case. This is especially true in the case of higher voltage lines because of the higher insulation level of these lines.

The data presented in table V are interpreted by the author as indicating that the tower design shown in figure 2 of the paper results in very efficient lightning operation. Double circuit construction similar in design to that shown in figure 2 but with the ground wire elevated 12 feet above the conductor in the suspension position, has been operated by the Hydro-Electric Power Commission for a number of years. The operating record of these circuits, however, is not considered to meet modern standards, in fact, in recent construction the design of the tower head has been modified so as to increase the ground wire separation to 17 feet at the tower. It is expected that this change, which brings the design for shielding into accord with recommendations based on recent tests on model lines, will result in noticeably improved performance from this type of tower.

It may be of interest in connection with the problem of shielding, to record less than one year's experience in a single-circuit, 110-kv line, 103 miles in length, on which stringing of the overhead ground wire has been postponed in order to obtain operating experience of the performance of a line with practically no shielding.

The towers on this line are 85 feet in height, being spaced approximately 1,100 feet. Power conductors are spaced 15 feet horizontally. A single ground wire is to be located at the tower head, 25 feet above the center conductor in the suspension position. Prevention of outages from sleet forming on the wires as well as from lightning were first considerations in the design of the towers. The measured average tower footing resistance is approximately five ohms. One individual tower had a resistance of 22 ohms and one of 14 ohms. These were the highest resistances measured at individual towers.

The line went into operation on July 4, 1940, and there have been 20 lightning outages to date. Six of these outages have been located. Of those located, all but one were at towers having footing resistance less than five ohms. This one had passed from the phase wire to the overhead ground wire of another 110-kv line passing underneath the line struck. The distance between the phase wire and ground wire was approximately 12 feet.

Although it would be unwise to draw any conclusions, using less than one year's lightning experience on the line as a basis, it is interesting to note that in at least 20 instances strokes to the line were of sufficient intensity to cause flashover of line insulation. It has been assumed that all strokes were to the phase wire initially, rather than to the tower, because there seems little probability that any of the flashovers were due to rise in tower potential, even if it is assumed that the tower impedance is somewhat higher than the measured resistance.

Data given in subsection XI are interesting. In one of the 220-kv transformer stations of the Hydro-Electric Power Commission there are installed six 220-kv lightning arresters. These arresters have been equipped since they were placed in operation with klydonograph surge recorders placed so as to record any discharge of lightning current through the arresters. In about 60 lightning arrester years of operation, not a single instance of recorded lightning discharge through these arresters has occurred. It should be pointed out that this station has what is considered better than average protection from direct hits in the vicinity of the station. Assuming that the author's data on lightning stroke frequency can be applied, the shielding network over the station and for one mile out on the line should have been hit from 20 to 30 times in the ten years of operation. The absence of a recorded lightning arrester discharge is a measure of the efficiency of shielding.

E. H. Grosser, Jr. (nonmember; Commonwealth Edison Company, Chicago, Ill.): This paper contributes data on some of the factors that enter into the engineering of lightning protective measures for overhead transmission lines. Some of the measurements made, as of tower currents, merely add to data previously obtained along similar lines. Little information, however, has been available heretofore on probable number of strokes to lines. As far as we know, the previous literature on this subject consisted of 1937 Paris conference paper 338, giving early surge current records for the Pennsylvania Water and Power Company lines and the Lewis and Foust data in AIEE TRANSACTIONS, volume 56, 1937 (January section), pages 101–06. These earlier figures indicated a probable average of about 85 strokes per 100 miles per year. The average reported in the present paper is almost 50 per cent higher, and should have some effect on line design.

With reference to Waldorf's comparison of calculated probable outages and actual outages, these can hardly be said to indicate wide discrepancies. Actually the performance records presented appear to show a fairly good agreement with calculated performance, when we consider the approximate nature of the prediction and the many assumptions made in the calculations. Among these may be mentioned: uncertain surge impedance of the lightning stroke; uncertain coupling factors due to corona effect and depth of current ground plane; unpredictable stroke characteristics which involve effect of tower height on tower-top voltages and have an important bearing on flashover voltages of line insulators and mid-span insulation; the consideration of counterpoises as pure leakage resistances; estimation of probable number of strokes to the line, etc. Even the disagreement between the author's data and the 1939 data of Lewis and Foust on distribution of tower lightning currents may introduce a factor of two or more. This particular factor becomes more uncertain for the higher currents, which would indicate that there is probably more chance of making an accurate prediction of performance for a medium-voltage line than for a high-voltage line designed for few lightning outages.

It would be of interest to know whether the calculated figures shown in Waldorf's table VI were complete analyses, or if they included only the effects of strokes to towers. We found, in design calculations for the Powerton-Crawford 220-kv line, that mid-span strokes assumed importance as the protective level of the line was increased, e.g., by added insulation or lowered footing resistance. In other words, for extra high-voltage lines, it seems necessary to consider the effect of strokes to mid-span even to the extent of providing, as we did, increased separation at mid-span between phase wires and ground wires. It is possible that this may account for the differences between the calculated and observed line operation reported in this paper.

It seems desirable to clarify one point regarding the shielding effect of overhead ground wires. Where two ground wires are used, for example, to protect three conductors in horizontal configuration, the center phase conductor should be almost perfectly shielded with nearly any practical placement of the ground wires. This readily follows from a consideration of the geometric arrangement of ground wires and phase wires with respect to the discharge center of the cloud. This effect is indicated to a certain degree in Waldorf's figure 3, but it is probable that a safe protective angle for the middle conductor can be even greater than the 41-degree angle shown.

One conclusion of particular interest may be drawn: that a virtually lightning-proof line is now a practical reality. For economic reasons, this end is normally attainable only for extra high-voltage lines. Where service continuity demands, however, such performance may be obtained on lower-voltage lines, by adequate design.

A. O. Austin (Manufacturing Engineer, Barberton, Ohio): The paper presented by Mr. Waldorf covering lightning performance on the transmission lines of the Pennsylvania Water and Power Company provides information of great value not only for improving existing lines, but as a guide in constructing new transmission systems.

The investigation carried out on the lines of the Pennsylvania Water and Power Company over a period of years has been exceptionally complete, and the electrical profession is indebted to the members of the organization and the company for making this information available. Information such as that presented by Mr. Waldorf, and by Messrs. Sporn and Gross covering the operation of the American Gas and Electric Company lines, can be used very effectively in analyzing different types of transmission line construction and determining the relative as well as probable performance of same.

The paper covers the method of improving the performance of existing lines by lowering the ground resistance or impedance, the other factors such as electrical exposure and length of span being fixed.

If the performance of transmission lines is analyzed, it will be seen that length of span and exposure as well as arcing voltage are very important factors in providing reliability. These factors can be used very effectively for constructing a new line, but are not easily applied to an existing system.

The studies made on the Pennsylvania Water and Power Company's system show the value of reducing the ground resistance or impedance by the use of a counterpoise, which is the easiest method of improving many existing lines.

The discussion and the tables call attention to the value of insulation or arcing voltage in preventing tripouts, as the highly insulated lines are practically free from tripouts even though these lines have a higher exposure and greater length of span.

With most types of transmission line construction an increase in the arcing voltage requires a material increase in the size and cost of the structure, and, furthermore, increases the exposure. For this reason much attention has been given to improvements in transmission line design, which will make it possible to increase the arcing voltage without an adverse effect upon the other factors.

The number of tripouts on some systems have been reduced to a very small percentage by using wood arms to increase the arcing voltage. Where both increased arcing voltage and lower ground resistance are provided, it is evident that the reliability can be greatly increased, and in many cases a higher operating voltage can be used to advantage.

It is interesting to note that Mr. Waldorf has estimated and compared the probable number of flashovers to the service record. The close agreement shows that it is possible to predict the probable performance with a fair degree of accuracy.

Developments in insulation during the last few years have made it possible to develop a higher arcing voltage for many of the two circuit structures, so that not only can tripouts be reduced, but higher operating voltages can be used without causing radio interference.

The relative performance of different types of construction can be readily obtained by taking into account the electrical exposure, ground resistance, length of span, and arcing voltage. To obtain the probable number of interruptions it is necessary to take the length of the line into consideration and the probable number of hits to the system. In other words, the probable number of tripouts can be represented by the following equation, where K depends upon the general storm conditions, L the length of line, E the exposure, G the ground resistance, and FO the flashover:

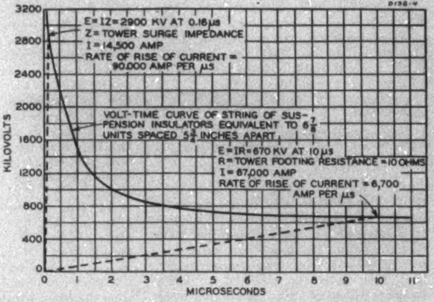
$$K\frac{L\times E\times G}{FO}=\text{probable number of interruptions}$$

A study of the various factors shows that it is possible to modify the type of structure and line to advantage in many cases.

An increase in the arcing voltage requires an increase in the size and cost of the structure. This in turn increases the electrical exposure; therefore much attention has been given to types of construction and insulation which will make it possible to obtain increased arcing voltages to ground without increasing the size of structure and exposure.

While the applications are limited, operating experience shows that much can be expected where all the various factors are given consideration, and it is hoped that more data along the lines given in the paper by Mr. Waldorf will be available.

Figure 4



K. B. McEachron (General Electric Company, Pittsfield, Mass.): In section VII under the heading "Flashovers," Mr. Waldorf suggests the possibility that, for currents in excess of 60,000 crest amperes, the rate of change of current is sufficient to produce an inductive drop great enough to cause flashover of the insulators on 66-kv lines.

It is recognized, of course, that the magnetic link measures crest current values, and does not indicate rates of rise. To assume that currents in excess of 60,000 amperes cause flashover as the result of inductive drop, it is necessary to assume that the higher rates of current rise accompany higher crest values of current. However, I know of no published data which show this to be a valid assumption, although it may be regarded as being reasonable in view of lack of any data to the contrary.

In view of this situation, it seemed worth while to me to examine some of the conditions which might cause flashover. In the figure is given a volt-time curve equivalent to eight disks spaced $4^{3}/_{4}$ inches. This curve is based on data supplied by the high voltage laboratory at Pittsfield, and for times shorter than one microsecond no great accuracy is claimed. Using a tower height of 80 feet, a time of 0.16 microsecond will elapse before a negative reflection from the base of the tower could reach the top of the tower, assuming that a direct stroke made contact with the top. On the curve a time of 0.16 microsecond corresponds to a voltage of 2,900 kv. If the tower surge impedance is taken as 200 ohms, the current at flashover would be but 14,500 amperes, although the rate of rise is 90,000 amperes per microsecond. This rate is much beyond any value yet published, and since the indicated current is much below the 60,000 value indicated by Mr. Waldorf, it does not seem likely that the flashover is due to rates of rise of this order.

If slower rates of rise are examined, it is found that the inductive drop is not sufficient and flashover will not occur, remembering that the first negative reflection reaches the tower top in 0.16 microsecond. However, if a tower footing resistance of 10 ohms is assumed, then any current in excess of 67,000 amperes would cause flashover, while current values appreciably less than 67,000 would not in general cause flashover. One would expect, therefore, in view of the foregoing discussion, that the flashovers which Mr. Waldorf mentioned are more likely due to *IR* drop than to impedance drop.

S. K. Waldorf: Messrs. Austin, Floyd, Grosser, Wagner, and McCann enumerate the several factors which affect the lightning performance of a transmission line. The exact effect of each factor is not known in many cases, but it is significant and fortunate that existing knowledge of shielding, insulation level, tower footing resistance, and perhaps maximum safe tower current allows line performance to be predicted quite well. The several other factors which the discussers have mentioned apparently have little effect individually or as a group.

Mr. Beck requests more complete data on the currents which have been recorded in lightning arresters. In the table which follows are given the complete data on the discharges which have been recorded on lightning arresters connected to circuits having preventive protection. The current of 2,600 amperes recorded in the arresters of the Holtwood-Baltimore lines in 1937 occurred before counterpoise had been provided.

With regard to the accompanying table the four 132-kv circuits have operated without difficulty for the indicated periods without any lightning arresters. Three years ago arresters were provided on *P*5 and *P*6 circuits because two new circuits were connected to them which were not so well protected as are the original ones. While it is recognized that discharges can occur through lightning arresters connected to lines having preventive protection when flashovers occur in the vicinity of the arresters, it is believed that the currents recorded at Highlandtown substation may be due to the arresters there being of the electrolytic type and the magnetic links may have been slightly magnetized during some of the daily power charging cycles. The records on the arresters connected to 13 and 14 circuits, which comprise the Holtwood-Coatesville line, were obtained in a year when expulsion gaps and no counterpoise were installed on three towers near the Holtwood station. The complete record, therefore, justifies the opinion expressed in section 10 of the summary of the paper.

Mr. Floyd suggests another basis for calculating the efficiency of protection provided for a transmission line. Even though no special measures have been provided to prevent lightning interruptions on a given line and some strokes do not cause flashover, it is apparent that protection is being provided even though the design did not include features for that specific purpose. For this reason, and in the interest of simplicity, it is believed that the method suggested in the paper for computing efficiency of protection will prove satisfactory. The other data presented by Mr. Floyd are valuable because they give additional information about the effects of the individual components of preventive protection and about the reduced duty on station lightning arresters when preventive protection is provided on the line.

Mr. Grosser points out that the uncertainty in the measurement of tower lightning currents affects the accurate prediction of performance for a high-voltage line more than for a low-voltage one. In addition to this uncertainty, it must be recognized that the probable outages on a high-voltage line are usually so few that it may take many years before the accuracy of the estimate can be properly compared with operating experience. Mr. Grosser also inquires whether all of the strokes to a line were included when the calculations for probable outages were made. All recorded strokes to the lines were used in the calculations. Just as the Powerton-Crawford line was provided with increased separation between phase wires and ground wires in mid-span, the lines described in the paper similarly are constructed. Mr. Grosser is quite justified in believing that the safe protective angle for a middle conductor in a horizontal configuration can be appreciably greater than shown in figure 3 of the paper. The angle of 41 degrees given in figure 3 is merely the minimum required to shield the inner conductor on the tower illustrated and, if model tests have any significance, probably can safely be made greater.

Dr. McEachron suggests that resistance drop more likely accounts for all of the flashovers listed in table III of the paper than does impedance drop. This may possibly be correct, but the difficulty arises in determining what is the resistance that is to be used in performance calculations. It has been the practice of the Pennsylvania Water and Power Company to include in its ground resistance measurements all auxiliary grounding, such as counterpoise, within one span length of any tower foundation to be measured. When this is done, the resulting resistance does not account for the flashovers in about 50 per cent of the cases which have been noted up to and including 1940.

Messrs. Wagner and McCann have submitted additional interesting analyses of the data obtained on the Pennsylvania Water and Power Company system. The third item which they have listed among the factors affecting lightning protection has been found to be of little importance. It is perhaps surprising to note that records obtained over a period of some years indicate that the ground resistance of counterpoise in the territory studied varies not more than about 10 or 15 per cent from season to season.

In answer to the question of Mr. Von Voigtlander, no oscillographic data have been obtained which would give information about the source of the apparent reactive effects which cause tower flashovers.

Discharges Through Lightning Arresters Connected to Circuits Having Preventive Protection (Including 1940)

A New Principle of Cable Design

Discussion and author's closure of paper 41-71 by Wm. A. Del Mar, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS (May section) 1941, pages 206–10.

L. F. Hickernell (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.):

EVOLUTION OF GRADED INSULATION

The range in characteristics available in modern cable insulating paper is indicated by the typical data in table I (of this discussion).

From these data, it is evident that as the specific gravity (density) of paper is increased, the physical properties change over a range from 25 per cent (modulus) to 8,700 per cent (air resistance) and the electrical characteristics, from 25 per cent (SIC) to 29 per cent (dielectric strength).

These interrelated physical and electrical properties of paper have created a fertile field for the development of design theories and for the exercise of ingenuity in the patent office. An indication of this productivity is shown in table II (of this discussion).

From this outline, it would seem that practically every combination of high- and low-density paper has been covered by one or more theories, electrically and mechanically. Attention is directed to one vacant space on the chart; namely, the justifica-

tion of "sandwich" grading on a mechanical basis. Thus, opportunities for imagination in the field of grading still exist, unless our researchers have missed a reference. Consequently, we will await with interest a future paper covering this missing link.

Analysis of Data

So much for historical background. The remainder of this discussion is devoted to an analysis of the data under the same headings and in the order established by the author.

Relative Imperviousness of Impregnated Paper to Oil Flow

In analyzing figure 1 (of the paper), it should be kept in mind that although the viscosity is shown in terms of Saybolt universal seconds, the actual values above 3,500 seconds were *not* measured on a viscosimeter. In other words, over five-sixths of the curve was obtained by *converting* to Saybolt units, measurements which were obtained under a different procedure. This conversion may be entirely justified. However, from the shape of the viscosity-temperature characteristics so obtained on Habirshaw compound number 7, the procedure would seem to be somewhat questionable. (This point will be discussed in greater detail by Greenfield.)

Elastic Properties of Cable Paper

The author states that different papers have different stress-strain characteristics or moduli. In figure 3 and figure 4 (of the paper), data are shown on type *N* (normal) paper. Since the proposed theory is based upon the *difference* in physical properties between *two* types of paper, it would seem desirable to include data on type *S* (special) paper also. Fortunately, such data are available in the author's patent (U. S. patent number 2,190,017) so that we may have some idea of the quantitative values involved. These data are reproduced in figure 1 (of this discussion).

Reference to figure 1 indicates that over the operating range, say 0 to 5,000 pounds per square inch, the difference in elongations between type *N* and *S* papers is from 0 to 0.1 per cent. In view of the disclosed permanent set in *all* types of paper, this would seem a very small quantity upon which to rely for continued benefit during the life of the cable. Creep under repeated stress also should be considered.

In evaluating this construction, the factor of unequal thickness contractions of two different types of paper should be taken into account. Before drying, the inherent moisture content of the two papers of different densities (or moduli) will be different. Hence, when the cable is dried prior to impregnation, the thicknesses will shrink in different proportions (refer to table I of this discussion). This effect may well mask the small difference in moduli.

Accelerated Aging Tests

Equivalence of Tests Based on Equal Maximum Stress. The author states that "To ensure that our tests should be equally *correlated with service conditions,* we decided to make our tests at the *same maximum stress* as in the Halperin-Betzer tests; namely, 208 volts per mil. . ." This statement is based upon two assumptions; namely that:

1. **The Roper-Halperin-Betzer aging tests, which bore a correlation with service conditions, were conducted at *208 volts per mil* maximum stress.**

Table III. Test Voltage Stresses for Cyclic Aging

1-Conductor 750-Mcm 66-Kv Cable, Commonwealth Edison Company

Group	Year	Author	Insulation Thickness (Mils)	Test Voltage: Times Operating	Test Voltage: Conductor Sheath (Kv)	Voltage Stress: Max. (VPM)	Voltage Stress: Avg. (VPM)	Copper Temp. (Deg C)	Remarks
A	1933	Roper	750	1¹/₂	57	124	76	60	Too slow
				2	76	165	101	{50 to 85}	Correlation with service
				3	114	248	152		No correlation with service
B	1936	Halperin and Betzer	750	1³/₄	67	145	89	R.T.+40	Best—too slow
				2¹/₄	86	187	115		
				2¹/₂	95	$\boxed{208}$	127	65	Eliminates poor in 4 weeks
C	1936	Halperin and Betzer	688	1³/₄	67	154	97	R.T.+40	Best—too slow
				2¹/₄	86	198	125		
				2¹/₂	95	218	138	65	Eliminates poor in 4 weeks
D	1936	Halperin and Betzer	625	1³/₄	67	165	107	R.T.+40	Best—too slow
				2¹/₄	86	212	138		
				2¹/₂	95	234	152	65	Eliminates poor in 4 weeks

2. If the author's test were conducted at the *same maximum stress*, the same correlation with service conditions would hold.

The calculated voltage stresses used in the Commonwealth Edison tests are shown in table III (of this discussion).

From this table, it will be noted that the maximum stresses varied from 124 to 248 volts per mil. Only one of the series was conducted at 208 volts per mil; namely, group *B*. This specific value was obtained when 2¹/₂ times operating voltage or 95 kv as applied to 750 mils of insulation. In view of these data, it would be interesting to know why the author happened to select the *lowest* maximum stress corresponding to 2¹/₂ times operating voltage.

Incidentally, it is our understanding that the Commonwealth Edison Company have selected 2¹/₂ times operating voltage or 95 kv as the proper test voltage for 66-kv cable regardless of what insulation thickness is offered. Hence, the bench mark is actual test voltage, not maximum stress.

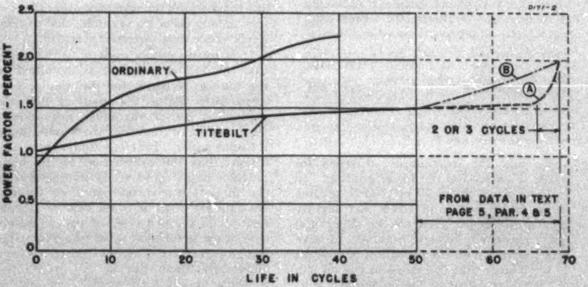
The maximum stress of 208 volts per mil in the Chicago tests, resulted from applying 2¹/₂ times operating voltage or 95 kv to a 750,000-circular-mil, 66-kv cable having *750 mils* of insulation. The selection of 208 (corrected) volts per mil maximum stress by the author to apply on his number 4/0 AWG, 17-kv cable having *220 mils* of insulation resulted in a test voltage of 32.5 kv or approximately three times the operating voltage (17/1.73 = 10 kv) of his cable. As the author points out, Roper found that for 66-kv cable, tests at three times operating voltage bore no relation to service records.

This seemingly paradoxical situation arises from the attempt to test a number 4/0 AWG (212,000-circular-mil), 17-kv cable with 220 mils of insulation at the same maximum stress used on a 750,000-circular-mil, 66-kv cable with 750 mils of insulation; the conductor diameters being 528 and 998 mils, the insulation thicknesses 220 and 750 mils and the geometric factors ($\log_e \times D/d$), 0.603 and 0.916 respectively. Due to this difficulty and because operators usually feel that a simulated service test should bear some relation to operating voltage, the equivalence of tests based on equal maximum stresses have not been accepted generally by the industry. For these reasons, it would seem to be on safer ground to base this type of test on average stress or operating voltage.

Stability Limits. The voltage stress at which the power-factor limit of 2.00 per cent at 85 degrees centigrade is obtained is not stated. Reference to figure 6 (of the paper) would indicate that this measurement is at rated voltage or 10 kv, corresponding to an average stress of 45.5 volts per mil.

Stability of Set Number 2. For set number 2, the tabulated data show that the Titebilt construction reached the power-factor limit (2 per cent at 10 kv and 85 degrees centigrade) in *69 cycles.* These data are shown graphically in figure 6 (of the paper). Unfortunately, the curve for the Titebilt cable is not shown above *50 cycles.* Thus the reader is forced to speculate on the portion of the curve between 50 and 69 cycles, as shown in figure 2 (of this discussion).

Figure 2. Life-cycle tests (compound 7)



The paper states that "the Titebilt cable shows a *smoothly rising* curve which contrasts remarkably with the erratic curve of the ordinary cable. The power-factor curve of the Titebilt cable did not show any final upturn until *two or three cycles before 'failure.'* "

If the term "failure" means reaching the limit of two per cent power factor in the final two or three cycles, presumably the slope would be similar to curve *A*. If the term "failure" applied to final breakdown, then the slope might approach that shown in curve *B*. In any event, the power factor rose from 1.5 to 2 per cent or 0.5 per cent in 19 cycles whereas it took the initial 50 cycles to rise the same amount (1.0 to 1.5 per cent). This would hardly indicate a "smoothly rising" curve, but, on the contrary, instability.

It is probable that, if the tests were conducted for a longer period of time, the results would confirm those obtained on a similar design of inverse-graded cable by Scott of England ("Long Period Aging Tests on Solid-Type Cables," by T. R. Scott, *Journal* IEE (British), volume 85, number 511, July 1939, page 67—Cable EC58/1a).

Compound Number 8

Although no viscosity characteristics are given, presumably compound number 8 with 10 per cent of hydrogenated wood rosin is a less viscous impregnant than compound number 7 with 15 per cent of natural wood rosin. If so, this factor may have some influence on the behavior of the Titebilt cable.

It is stated that there was no indication the Titebilt cable with compound number 8 would attain the power-factor limit in 200 cycles. It would be interesting to know if ordinary cables with compound number 8 showed comparable improvement.

Commonwealth Edison Test Procedure—1939. Again, it is not our understanding that the Commonwealth Edison Company tests reported by Halperin in 1939 ["Load Ratings of Cable," by H. Halperin, AIEE Transactions, volume 58, 1939 (October section), pages 535–53] are based on any specific voltage stress such as 114 volts per mil, average and 195 volts per mil, maximum as stated in the paper. The 1933–36 tests, discussed above, were on 66-kv cable and the test voltage was $2^{1}/_{2}$ times operating voltage or 95 kv. The 1939 tests were on 12-kv cable and the test voltage was two times operating voltage or 24 kv. Accordingly, in both cases the criterion is an actual test voltage related to operating voltage and not average nor maximum stress.

On this basis, the 114 volts per mil average stress, mentioned in the paper, would apply only to a shielded cable having 122 mils insulation. Shielded cables with as low as 100 mils have been subjected to the same test voltage or 24 kv with the resulting average stress of 139 volts per mil.

Shielded Three-Conductor Cable

On the basis of being offered for the same operating voltage (12 kv), it is, of course, interesting to compare the test results obtained on Titebilt shielded cable having 122 mils of insulation with belted cable having $9\times{}^{5}/_{64}$ inches (141×78 mils) of insulation reported by Halperin in 1939. Since 1939, tests on the same procedure have been conducted on two new designs of shielded cable as reported in the technical press ((1) AIEE Transactions, volume 59, 1940, page 1041 and (2) *Electric Light and Power*, July 1940, page 34). It would be interesting to compare the results obtained on the three different designs of shielded cable tested under the same procedure. Unfortunately, it is impossible to do this owing to the omission, in table I (of the paper), of any of the power-factor values above 60 degrees centigrade (i.e., for 80, 100, and 115 degrees centigrade). The absence of other data usually obtained on this type of test, such as pressures, vacua, and sheath expansion, are noted. In addition, the dielectric strength obtained on the AEIC specification sample tests (high-voltage time and cold bend) would be of interest.

To assist the industry in evaluating this construction, it is suggested that the author include in his written closure, the aging data mentioned above. Preferably, this should be in the form established by Halperin in figure 1 of his 1939 paper, and followed by others, in order that the data may be directly compared.

Robert J. Wiseman (The Okonite-Callender Cable Company, Inc., Passaic, N. J.): In the reading of Mr. Del Mar's paper, several questions arise which may help us to appreciate the design of cable which he proposes. It is true that the viscosity of the oil used in solid-type cables is high enough to cause high local internal pressures and these pressures may result in stretching of the paper, enough to take up the increase in volume of the oil. This stretching is more effective on sector and oval-shaped conductors than for round conductors. In the latter case the oil also flows more easily between the tapes to the gaps and out to the sheath. The idea of the oval-shaped conductor for both single and multiconductor cables is based on the theory that the tapes along the minor axis are stretched as the temperature increases and when the cable cools down they return to place, forcing the oil into the inner portions of the insulation. We have tested single oval-shaped conductors and have obtained pressures of 20 pounds per square inch at the sheath when for a round conductor we obtained as high as 85 pounds per square inch. Therefore, any means we have to allow the paper to stretch during the heating of the cable is good for the cable. Has Mr. Del Mar compared tests with round and sector or oval conductors?

I am curious about figure 1. I would like to know more about the method of test and also how Mr. Del Mar obtained such high viscosities. Oil will start to flow very shortly after load is applied to a cable. We have measured 100 pounds per square inch pressure at the conductor one-half hour after load is applied and the pressure at the sheath had not increased. Two hours later the sheath pressure was 85 pounds per square inch. In this case, the conductor temperature had not increased very much in one-half hour.

I would like to see comparative physical properties of the normal and special papers Mr. Del Mar uses in order to appreciate their relative moduli. At the time of the issuance of his patent he showed curves of stress and strain. A comparison with superdense paper and normal paper we are using showed very close similarity. I also would like to know the relative oil absorption of both papers and their specific inductive capacities. I believe he has a reverse gradient cable with its accompanying distribution of electric stress. The difference in comparison to usual gradient will not be very great because of the thin walls involved. In addition, we must consider the electric stress in the oil gaps for the two papers because of the relative specific inductive capacities. If we take as an example the three-conductor, 500,000-circular-mil cable described, and round conductors, an SIC of 4.2 for impregnated special paper, 3.7 for normal paper, and 2.2 for oil, we get the stresses at various positions as shown in the following table:

	Stress at Conductor Surface (Volts Per Mil)		Stress at Beginning of Outer Zone (Volts Per Mil)	
	Paper	Oil	Paper	Oil
Type N inner zone	136	220		
Type S outer zone			101	193
Type S inner zone	129	246		
Type N outer zone			122	204

We find the distribution of stress for paper is better for the usual grading. In the case of oil, the usual method of grading shows higher values of stress and slightly greater difference between the inner and outer zones, not enough, however, to have much influence on the operation of a cable. If we assume that the stress in the oil gap is the major factor in the breakdown voltage of a cable, then we should expect Mr. Del Mar's cable to give higher values than the usual grading. Has Mr. Del Mar made comparative tests?

This cable appears to me to be similar to the "SR" cable put out by the Standard Telephones and Cables Company of England. This cable functions on the assumption that if we have papers with different degrees of oil absorption, with the highest absorption next to the conductor, as the cable cools down, the oil is drawn by capillary attraction to this zone, thereby maintaining better saturation of the cables for all temperatures and better operation.

I would like to see the power factor-temperature curve for the cable referred to in table I of the paper and also the power-factor time plot for all temperatures up to 115 degrees centigrade. The cable operates at higher temperatures than 60 degrees centigrade and, therefore, should show stability at the higher temperatures. How much negative ionization did Mr. Del Mar get at the various temperatures? What pressures and vacuum did Mr. Del Mar get on this cable? If I understand his design correctly, there should be very little, if any, pressure between the cable and sheath when the cable is heated because the oil is not permitted to leave the insulation. Therefore, there should be no lead sheath expansion and when the cable cools down, no vacuum created.

J. B. Whitehead (The Johns Hopkins University, Baltimore, Md.): The results reported by the author for the performance of the Titebilt cable are very impressive. This is especially true of the test of sets 1, 2, 3, and 4. Moreover, the results of examinations after the tests and the performance reported for compound 8 are also very striking.

In view of the superiority claimed for the Titebilt principle, it becomes important to examine the basis upon which claim is made. It is also of great interest to examine the principle which the author invokes to explain the results of his tests. Unfortunately the paper is not completely satisfactory in either of these respects. First as to the test themselves, one would like to know the spread of the results as observed among all the cables tested, the range of initial power factor, and the density and dielectric constant of the several papers studied. Moreover, the program of the test itself is of highly special character, and one would like to have seen the results of other types of test, among them for example, that of relatively short-time dielectric strength.

It is by no means evident in the paper that the Titebilt principle as described by the author accounts for the test results. Apparently the author assumes that the permanent set of the inner low-modulus paper is greater than that of the outer high-modulus paper. It is only under these conditions that the contraction of the high-modulus paper could act in compression on the inner low-modulus paper on cooling. No data are given as to the relative permanent set of the two types of paper. Moreover, if the permanent set of the inner paper constitutes the trouble to be corrected (and apparently there can be no other) this would be absent in the samples constructed entirely of type *S* paper and it should show an equal, if not better, performance than the Titebilt sample.

It appears, therefore, that some other elements than that of the elasticity of the paper are entering to account for the superior results shown from the Titebilt samples. Here again, however, we are in difficulty because of insufficient information furnished by the author. Most cable engineers now agree that initial instability and ultimate failure is caused by the presence or liberation of gas in the oil channels and films. It has recently been shown that in thoroughly impregnated specimens the stress in the oil channels, the stability, and the breakdown strength are greatly influenced by the density of the paper. Breakdown strength and life in accelerated tests are both reduced by increasing paper density. These results are clearly explained by the difference in the dielectric constants of the impregnated paper and the adjacent oil channel. The author of the present paper has not given sufficient data as to either density or dielectric constant to make possible a computation of the relative stresses in the oil channels of his various specimens. One would also like to see points indicating experimental observations on the curves of figures 1, 3, 4, and 6.

With so many variables present in a completed cable, it appears possible that there may be others than those mentioned which also have a bearing on the results found. For example, may it not be that the Titebilt samples were actually more tightly wound than the others?

It is to be hoped that the author will supplement the present interesting paper with further tests and further analyses of the results.

T. F. Peterson (American Steel and Wire Company, Worcester, Mass.): The new design of paper-insulated cable appears to be predicated on the existence of two phenomena which are very difficult for me to accept, namely:

1. In solid-type cable there is substantially no outward flow of oil or compound at ordinary operating temperatures.

2. High modulus of elasticity paper-belt insulation holds inner layers in compression and, after heating, restores inner layers to original condition.

Certainly, figure 1 of the paper does not prove the absence of radial flow. It shows that the flow is slow. Is not this particularly conducive to "ratcheting" out of oil? If there is no radial flow of compound, what has caused lead sheath stretching which has been so prevalent in recent years, and has occupied the attention of operating engineers because it appeared to be so serious?

Now, as to the operation of high-modulus paper in restoring inner paper volume: I contend that the value of modulus has little to do with the degree of restoration unless the outer belt is also "truly elastic" in its stress-strain diagram, that is, unless this is a straight line through the origin both for rising and falling stress. "Creep" or "permanent set" when stress is removed would preclude usefulness of high-modulus paper in restoring inner paper volume. The author indicates that "all papers tested showed more or less permanent set." It seems unfortunate that the "modulus" and "permanent set" curves were given only for so-called normal paper and not for the paper responsible for the remarkable characteristics of the newly designed cable. If the subject were treated mathematically, I think it would be found that even a "low modulus" binder or belt would serve the intended purposes, provided it had negligible permanent set after removal of stress.

Finally, if compound does not move radially, paper does not stretch enough to create oil passages between layers, and high-modulus paper does develop a "permanent set," why not use a truly elastic binder in the form of a hard drawn copper tape or synthetic rubber-like sheath? Quite obviously, some improved characteristics of single-conductor cable have been observed on accelerated life tests. If high-modulus characteristics of paper do not fully explain the improved results, could they be attributed to "inverse grading" with high SIC paper in the outer region contributing to reduced stresses in oil of gaps in paper nearer the conductor?

E. W. Davis (Simplex Wire and Cable Company, Cambridge, Mass.): We have read with considerable interest the paper by Mr. W. A. Del Mar—"A New Principle of Cable Design." The test data submitted would indicate a definite improvement in cable quality, although the discussion of the theories involved in this improvement may be questioned by some engineers and physicists.

We do not completely understand the significance of figure 1. Apparently the rate of pressure transfer is shown for only one constant pressure on one side of the wall of paper insulation. Would not this rate of pressure transfer be a function of both the paper thickness and the value of the constant pressure applied? Being a function of two variables, might not there be a decided change in the shape of the pressure transfer curve?

The meaning of reference to paper stretch is not clear. If the elongation of the paper is not enough to leave oil passages between layers as stated by the author, how can the permanent set be enough to leave voids in cooling if as indicated by figure 3 and figure 4 the set is only one-tenth of the elongation? A space ten times the thickness of the voids should allow the passage of oil or inversely one-tenth of a space too small for passage of oil must be rather small even for a void.

The outer layers of paper are 20 per cent higher in modulus of elasticity than the inner layers. This modulus is stress/strain or the inverse of the slope of the curve of figure 3. Figure 3 shows an elastic limit at about 3,000 pounds per square inch, the modulus being constant below this value and decreasing above it. The higher modulus of the outer paper means that a greater stress is necessary for the same deformation, or less deformation of the outer paper than that of the inner paper for any given stress. We follow the author's explanation this far with no trouble but we find no reference to a difference between the papers that seems important to us. How do they compare as to permanent set? Do papers of higher modulus have correspondingly less permanent set? How does the permanent set-elongation relation of figure 4 vary among papers of different modulus? The squeezing action of the outer papers, especially after several cycles, may be limited more by the permanent set than by the modulus. One is tempted to wonder about the permanence of the improvement if it is due to higher modulus. Presumably, this higher modulus would be called into play at each load cycle. What might happen after 2,000 load cycles? Would the paper still retain its high modulus or would it have become permanently set? Stress-strain data on this paper would be interesting and also any data on fatigue. There is no mention of the well-known fact that it is more difficult to close a void with expansion than to form it initially. Often such a void will withstand appreciable positive pressure before disappearing. Instead of helping "to restore the inner layers to their original condition" the effectiveness of the outer layers may be due to this extra mechanical pressure.

Another explanation may be that high-modulus paper merely reinforces the inner layers preventing them from stretching. Therefore, the oil is forced through the channels between the tapes instead of stretching the paper.

We would like to ask the author if the two papers have differences other than the modulus. Are they appreciably different in air resistance, dielectric constant, or dielectric strength for instance? It is not impossible that some such difference may be an unexpectedly large factor in the cable behavior.

The work with a new impregnating compound is interesting and illustrates the possibilities of newer materials. However, the implications that this compound makes better performance because of its higher resistance to bombardment may or may not be correct. There are two schools of thought as to start of cable failure—

1. That failure is due to cold glow discharge in gaseous voids,

2. That failure is due to ionic bombardment from the conductor when the cable is hot.

From these points of view the conclusion is justifiable, but past laboratory experience has shown equally surprising improvements from changes to compounds not of superior resistance to bombardment providing such compounds are more suited to the particular paper used. We feel there is much to learn yet about combinations of paper and oil under various conditions. Is it not possible that the new compound fitted the particular paper porosity and cable structure better irrespective of its resistance to bombardment?

If this is not so, then we are forced to conclude that even the present improved cable has gaseous ionization or ionic bombardment present, and while life tests show it to be superior, will this superiority be attained in service?

Life tests have distinct value as have similar accelerated aging tests on other insulations. However, experience shows such accelerated tests must be carefully examined and interpreted in the light of service conditions to be sure such tests contain no elements leading to erroneous conclusions. This is particularly true of life tests on paper cable where overvoltages and artificial load cycles can make many changes in such a complicated structure as paper and oil.

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.):

Mechanical Stresses Within the Cable

This paper is based upon the conception that solid-type paper cable deterioration is fundamentally due to vacuous gaps formed in the cooling cable as a result of excessive pressure on the paper insulation occasioned by the expanding but viscous oil during heating periods. The author arrives at this conclusion from observations of stress-strain and permanent set characteristics of impregnated paper in which he shows for one type of paper the permanent set to be about one-tenth the elongation for any tensile stress (figures 3 and 4). The paper states that "from calculations of the paper tension arising from oil expansion," it is found that permanent set of the paper is sufficient to leave voids on cooling. This point is considered of utmost importance in the mechanisms of the author's design and hence is worthy of examination.

Since neither sample calculation nor method of evaluating the factors is given, it may be pertinent to inquire into the rigorousness of the author's conclusions. The theoretical problem of internally developed tensions is exceedingly difficult and it would seem obvious that an experimental solution would be more practical as well as desirable. The pressure drop across the insulation is a function of paper permeability and oil viscosity and both of these factors are functions of time. In addition to permanent set of the paper, the question of creep is involved and this again brings in the factors of pressure and time in complex relationship. The time factor apparently is neglected since no data nor statements concerning this are given by the author.

As an example of the confusion possible in the calculation of this problem, let us assume we know the form of the pressure distribution through the cable at any instant of time after start of cable heating. On this basis, the relation may be expressed by:

$$P_x, t = Kf(r, t)$$

where

P_x, t is the pressure at a point x in the insulation at a time t

r is the radius of point x from center of conductor

t is the time

The general formula for hoop stress or tension is:

$$\text{Hoop stress} = \frac{(D-T)}{2T} P$$

where

D is the outside diameter

T is the thickness of the serving bearing the pressure

P is the internal pressure

If we wish to calculate the hoop stress at a diameter D_x in the insulation, we must decide first whether a single tape is to carry the full stress, or all the insulation between the diameters D_x and D actually carries the stress. This makes a very large difference in the result. Calculating hoop stresses for both conceptions, we have:

For single-tape carrying stress:

$$S_{x_1} = \frac{D_x - T}{2T}(P_x, t) \qquad (1)$$

where S_{x_1} is the stress in a single tape.

If the remainder of the outer insulation carries the stress:

$$S_{x_2} = \frac{D + D_x}{2(D - D_x)}(P_x, t) \qquad (2)$$

where S_{x_2} is the stress in the rest of the insulation from point x to outer radius.

The ratio,

$$\frac{S_{x_1}}{S_{x_2}} = \frac{(D_x - T)(D - D_x)}{T(D + D_x)} \qquad (3)$$

That the ratio given by equation 3 can have large values is shown by the following example.

Consider a cable of 2.85 inches core diameter, made with 5-mil paper tapes and calculate the hoop stress existing at a point near the conductor, say at a diameter of 1.42 inches. Substituting these values in equation 3, we find the ratio of the stresses for the limiting conditions defined above to be approximately 100. Near the middle of the insulation, the ratio is approximately 80 to 1. Hence, in this case, the stresses borne by the tapes may vary by a factor of 100 to 1 or 80 to 1, depending upon the conception of how the insulation behaves and what point in the insulation we are considering. For normal, well-made insulation it is felt that the tapes act together in transmitting and resisting pressure and hence, the author's theories are not sustained. In 1927, Hochstadter and Barrat,[1] came to this same conclusion.

Development of Internal Pressure

The author states that the source of the excessive internal pressure in solid cable is the "oil viscosity which is so great that very high pressures are created by the expanding oil." In figure 1 of the paper is shown a curve expressing the rate of pressure transmission through 220 mils of insulation as a function of oil viscosity under a driving pressure of about 14 pounds per square inch. The temperature range covered by the curve is only from 60 degrees centigrade to 100 degrees centigrade, yet over this range, the viscosity of the oil is shown to vary from 25,000 seconds to about 200 seconds. We are asked to believe that at 60 degrees centigrade the rate of transmission of pressure is so low through the 220 mils of insulation that equilibrium conditions are reached only after 48 hours and at 100 degrees centigrade after about $1^{1}/_{2}$ hours. This is an enormous range of viscosity and indicates that the saturant is below its flow point (ASTM) at temperatures lower than approximately 65 degrees centigrade.

The author has indicated in his verbal presentation of the paper that the abscissa of his figure 1 is not Saybolt seconds viscosity as marked but rather consists of two types viscosity parameters. The first one-sixth of the abscissa is indicated to be Saybolt universal viscosity and the remaining five-sixths to be "seconds" obtained by penetration through precalibrated paper sheets. It is apparent that these two measures of viscosity are not consistent and that the viscosity function of figure 1 is discontinuous in the region of 3,500 seconds. Hence all the factual data of figure 1 are open to question.

It should also be pointed out that the rate of pressure transmission is a function of the driving pressure in addition to the oil viscosity.

Flow of oil through paper has been investigated extensively by many people, and in particular as to insulating paper, by Whitehead and Greenfield,[2] Race,[3] and Bull.[4] Regardless of whether the D'Arcy or Washburn equations of flow are used, it is known that under a given driving pressure, the rate of oil flow varies directly as the permeability of the paper and inversely as the viscosity of the oil. Since the pressure is transmitted by the oil, the rate of oil pressure is proportional to the rate of oil flow. Hence, conclusions concerning oil flow also define rate of pressure transmission.

The easier the oil can pass through the paper structure, the less pressure on that structure. Therefore, the simplest solution to the problem is to use tightly wrapped, high-permeable paper and low-viscosity oil. The author proposes and shows high-density, high-modulus papers near the sheath and a saturant of abnormally high viscosity (over cable operating range of temperature). These features only aggravate the pressure and insulation distortion possibilities in the cable. On this basis, there is considerable doubt that the improved results the author ascribes to his "Titebilt" construction are due to the mechanism he propounds.

It may be that the improved results shown to have been obtained in the few cycles of aging are due to the electrical effects of reversed grading rather than to any mechanical effect. By placing the lower density paper next to the conductor, the stress in the oil channels in that region is lower than if high-density papers were used. It cannot be emphasized too strongly that the oil channels are probably the weakest part of the insulation. There is now ample experimental evidence and more steadily accumulating to substantiate this point.

Compound 8

Although no viscosity-temperature curve is shown for compound number 8, it may be presumed that, having less rosin, it is probably less viscous than number 7. We wonder if the improved results reported for number 8 compound are not in part due to its lower viscosity as well as to better discharge characteristics. Since the author's tests are not influenced by compound migration, the lower viscosity oil will produce less pressures and permit more rapid and effective self-healing action in the oil gaps. It would be helpful if the paper included comparative viscosity-temperature curves for compounds 7 and 8.

John H. Palmer (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Mr. Del Mar's paper has dealt rather briefly with belted cables of Titebilt construction, and states that the benefits derived were smaller than those obtained in the single-conductor and three-conductor shielded types of cable.

This is true, if judged by the electrical measurements made. Comparison of Titebilt and old type cables of the belted construction by visual examination, however, after load-cycle tests, gave a very striking example of the effectiveness of Titebilt construction. This was shown by the relative conditions of the filler spaces and of the tapes adjacent to them, both in the belt and in the single conductors.

Results of examination are as follows:

The Titebilt cable, *A* in the photograph, showed only the initial stages of wax formation in the filler spaces. There were only one or two slightly charred spots in the fillers and surrounding insulation of the section examined, and this area remained unusually well saturated considering the treatment which the cable had received.

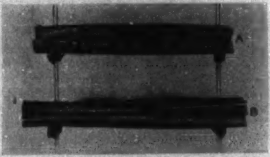

Figure 3. Singles and fillers of belted Titebilt cable (top) compared with belted graded cable (bottom) after 116 cycles of load-cycle test at temperatures of 85 to 100 degrees centigrade and 24,000 volts

Both cables impregnated with compound 7

Note good impregnation of Titebilt cable and dry burned waxy appearance of graded cable

The condition of the old type cable, *B* in the photograph, was about as would be expected. The filler spaces and several layers of the surrounding insulation both in the belt and on the singles contained a great deal of cable wax, charred spots, and dendrites. This area was also quite dry as is usually the case in the presence of much wax.

All other parts of both cables were in excellent condition.

The difference in these cables was so great, that it can easily be distinguished in the accompanying photograph showing the surfaces of the singles which were adjacent to the fillers. The high lights visible on the Titebilt conductors at the top of the picture clearly show the surplus of impregnating compound remaining in this cable.

These cables were of identical construction except for the types and distribution of the paper tapes used. They were impregnated at the same time and in the same tank, using compound 7 and were both subjected to 116 load cycles, giving copper temperatures of 85 degrees centigrade to 100 degrees centigrade.

The filler spaces have long been the weak point in belted cable, where deterioration normally starts. The Titebilt principle of construction has evidently improved conditions in this danger zone.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): Del Mar's test results speak for themselves, and show for the experimental conditions a definite superiority for his new construction over the constructions with which it has been compared. His tests, when considered together with the tests made at Chicago which he quotes, seem to be very strong evidence of the value of cable which he describes. However, Del Mar's theory of the results, which seems correctly to explain the *test* results, seems to me to discount the possibility of any permanent benefit from this construction, in terms of *life of cable in operation*.

Del Mar's explanation of the "Titebilt" cable is essentially that the outer layers of paper act effectively as an impervious elastic covering over the remainder of the insulation. Such a theory can readily explain successful results of short-time tests or even tests of the longest duration that Del Mar describes and yet be completely inadequate to correlate these tests with service conditions. Thus, a covering that is nearly tight but not completely so will function, for a time, in a manner substantially the same as a perfectly tight covering, but very slow oil flow through the covering will be cumulative over the period of months and years of the cable in operation and thus eliminate any permanent gain.

In order to permit judgment as to the significance of his tests with respect to operating characteristics, it is necessary to study quantitatively the actual flow of oil in a cable of the "Titebilt" type. The data given in figure 1 are not readily adaptable for such a quantitative study and accordingly we have, ourselves, made such measurements on a carefully prepared cable model.

The model was made on a smooth cylindrical mandrel and tightly hand-wound in a lathe. The tightness of wrapping was at least as great as is permissible on a cable that must be bent, and thus the resistance to oil flow at least as great as for a cable.

The wall thicknesses and types of paper used are those used by Del Mar on his shielded 3-conductor cable as described—90 mils of low-density paper and 30 mils of superdense paper. The oil used was also similar to one of those described by Del Mar, namely 85 per cent paraffin base cylinder oil of 150 seconds viscosity at 210 degrees Fahrenheit and 15 per cent rosin. The diameter of the insulated mandrel was approximately two inches.

After saturation, the radial oil flow through this sample was measured when internal hydrostatic pressure was applied. Measurements were made at temperatures ranging from 116 degrees to 43 degrees centigrade and at pressures of 100 pounds per square inch and 20 pounds per square inch. The values were found to be substantially proportional to pressure and inversely proportional to viscosity. Of 13 measurements made 10 were within 25 per cent of such proportionality while the remaining 3 were only 20 to 35 per cent of the proportional value. The values at different temperatures, as taken from the curve were as follows:

Temperature 0 Deg C	Oil Flow in Grams Per Pound Per Square Inch Per Hour Per Foot of Sample	Kinematic Viscosity (Centistokes)
116	1.35	25.5
76	0.27	122
58	0.093	340
43	0.033	1,000

One may apply the above measured values to the practical case of a cable heated so that the temperature of the outer layer of paper is 76 degrees centigrade. Assume a hydrostatic pressure of 75 pounds per square inch to be produced as a result of the expansion of the oil from heating. The rate of loss of compound per foot length on a cable one inch in diameter (one-half that of the above handmade sample) is 9.5 grams per hour, or about 0.17 cubic centimeter per minute. The total volume increase of oil due to temperature variation is less than three cubic centimeters per foot (two per cent of total volume). Of course the hydrostatic pressure in the cable will fall off as the oil moves out through the paper wall, and the rate of movement will decrease, but clearly a volume of oil equal to a large part of the expansion will go through the wall in a relatively few minutes under the conditions above described. At lower temperatures the rate of movement will be slower due to the higher viscosity of the oil. But, at any temperature at which there is an internal hydrostatic pressure and at which the oil behaves as a viscous liquid, there will be a continuous bleeding that will, during a reasonably short cable life, result in substantial cancellation of the special property claimed for the "Titebilt" construction.

Note that when the load changes from low to high there is relatively high pressure inside the insulation and relatively high temperature, while when the load changes from high to low the pressure and temperature are relatively low. Assuming that for a given temperature and a given pressure difference the rate of flow is the same from the conductor out as from the sheath in (which is substantially true), the actual rate of flow on cooling will be less than on heating, so that apparently some of the compound which gets through the insulation to the sheath will never get back into the cable. Moreover, the greater the absolute resistance to flow of the nonimpervious belt the greater will be this accumulation of compound on the outside.

Let us hope therefore for a new theory that will give some quantitative explanation of the test results found without, at the same time, indicating that these test results are of no practical significance.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Mr. Del Mar's paper is a stimulating contribution to the problem of solid-type high-voltage cable. While the good test results reported in the paper, and confirmed by tests on one sample in Chicago, seem to support the theory underlying this new construction, some of the theoretical considerations seem to be in conflict with observations we have made on cable after operation under test or in service.

Mr. Del Mar's theory assumes that for the heavy compounds used in solid cables practically no radial migration of compound occurs, but the expansion of the compound produces a permanent set of the paper. This theory is in contrast with the finding that frequently the gap under the sheath produced by expansion of the lead is well filled with compound while dryness is found in the body of the insulation. This finding indicates that radial migration of compound must have occurred. Also, if in solid cable the expansion of the sheath were produced only by expansion of the paper insulation rather than by radial migration of the compound, then on aged cable the diameter over the insulation should be found to have increased as much as the diameter over the lead. Actually we have not found this to be the case in the many measurements we have made on cables having appreciable expansion. For cables having large sheath expansion, we have found no appreciable change in the diameter over the insulation, although there have been some indications of slight changes in some cases.

The question as to whether oil can flow along the path between tapes is certainly influenced by the tightness of the insulation as well as the viscosity of the compound. The author points out that, while radial flow does occur with the thin oils used in oil-filled cables, practically no such flow occurs with heavy compounds used in solid cable. It should be noted, however, that the viscosity of solid compound at 80 degrees centigrade is about the same as that of oil-filled cable oil at 30 degrees centigrade. If radial flow of oil can occur in oil-filled cables at low temperatures, the same should be assumed for solid cable compound at high temperatures. Actually, as figure 1 of the paper shows, the rate of flow at 80 degrees centigrade is about one-eighth of the rate of flow at impregnating temperature.

At impregnating temperature the radial flow of compound is obviously large. This temperature is probably in the neighborhood of 100 degrees centigrade. As table I of the paper shows, the test cable was subjected to four cycles with a maximum copper temperature of 115 degrees. It is estimated that the corresponding sheath temperatures were 93 degrees and the average temperature of the compound 104 degrees. These temperatures are of the order of impregnating temperatures, and, therefore, it should be expected that radial flow could have occurred at least in these high-temperature cycles.

We have found occasionally some looseness of the insulation and signs of deterioration in regions where the direction of taping was reversed and we have not found these phenomena particularly associated with regions of change in density and kind of paper tapes.

The main point to me as a user of cable is, however, that the recent samples of cable so far made under Mr. Del Mar's technical direction have excellent characteristics in accelerated aging tests. Probably other factors besides the Titebilt principle help to produce this result.

K. S. Wyatt (Phelps Dodge Copper Products Company, Yonkers, N. Y.): In the novel construction described, improved load-cycle stability has been obtained by taking advantage of the elastic properties of cable paper. Careful study of this paper, however, leads to the conclusion that other factors have contributed to the high degree of stability attained.

In the first place there can be no doubt that the "Titebilt" construction does minimize ionization effects for at post-mortem examinations of samples of Titebilt and normal cable after severe load-cycle aging it is clearly evident that while dendrites and wax were present in considerable amount throughout the inner two-thirds of the insulation wall of the normal cable, there was a complete absence of ionization phenomena in the Titebilt samples except in the outer layers.

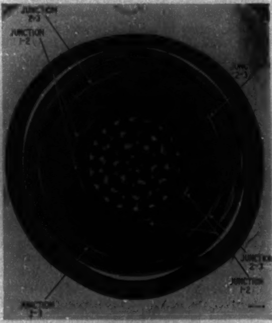

Figure 4. Wafer of new European cable employing dense paper at conductor, less dense in the middle, and still less dense at the outside

In the drying of this cable the different papers shrank away from each other, leaving annular gaps in which ionization may take place

However, I believe some of the improvement is due to another factor. Much cable today is graded with dense insulation next the conductor, less dense paper in the middle and still less dense at the outside. Among such papers of different density there is a fractional variation in SIC, so that when applied with the highest SIC (and highest density) paper next the conductor, the curve of potential gradient was supposed to be smoothed out somewhat, resulting in lower maximum stress at the conductor. With theoretical ideas such as these as a basis, the principle was employed in actual cable construction in Germany, from where it spread to other countries.

A surprising characteristic of cable graded in this manner came to light when it was "waferized" [AIEE Transactions, volume 57, 1938 (March section), pages 141–54]. It was found that at the junction of two different grades of paper, instead of there being close contact between the papers there was an annular gap (figures 1, 2, 3). The radial thickness of these gaps was far more than was necessary to ensure ionization in an operating cable when the compound drained from the gap (as it does in practice because no cable route is perfectly level). The presence of annular gaps and the obvious deduction that serious ionization must occur in them are supported by the common observation among cable engineers, that when a graded cable, after a period of service or accelerated aging is dissected layer by layer, wax in considerable abundance is frequently found at the junctions of the different types of paper. These annular gaps result chiefly from the fact that most dense papers shrink more longitudinally than lighter papers, so that upon drying a cable of composite insulation wall (prior to impregnation), the inner, more dense paper shrinks away from the outer, less dense paper. Thus the widespread practice of grading, based on theoretical considerations of small variations of SIC, neglected to take into account physical

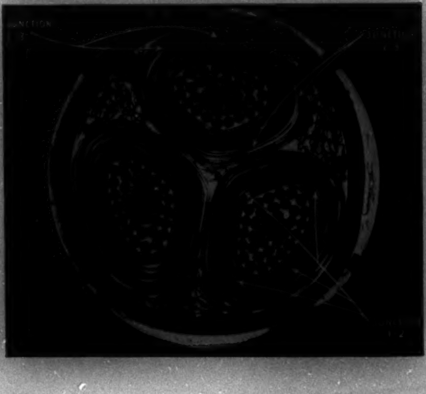

Figure 5. Wafer of 3-conductor 24-kv graded cable showing annular gap resulting from differential shrinkage of three types of paper employed

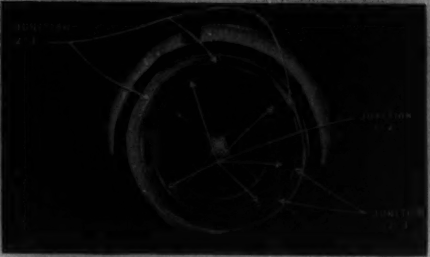

Figure 6. Wafer showing marked development of annular gaps resulting from paper shrinkage in a new cable with thick insulation wall

properties of major importance, and in consequence resulted, instead of in an improved construction, in a cable into which annular gaps or holes had actually been built.

The troubles encountered with grading seem to me to explain why Mr. Del Mar's cable has attained such a high measure of stability. Instead of placing the dense paper next the conductor, he builds his main insulation wall of normal cable paper and outside this he applies dense (high-modulus) paper. Thus when his cable is dried the outer layers of dense paper shrink more than the inner papers, thereby eliminating any gap at the junction of the papers and in fact, probably tightening and supporting the whole insulation wall. What Mr. Del Mar seems to have done, therefore is to follow the practice of a good blacksmith who shrinks the steel tire on to a wooden wheel, not to reverse, with the result that he obtains a tight, sound, and serviceable product.

It should not be inferred from this discussion that all graded cables contain annular hollow spaces within the insulation wall, because the shrinkage properties of paper could be controlled, and it should be possible, therefore, to make a tight construction even though normal grading is employed. There are many difficulties to overcome in practice, however.

In the above considerations differential shrinkage of cable papers, a subject which has occupied my attention for the past four years, is important. This is a broad subject which will be discussed elsewhere.

Mr. Del Mar's construction should result in a cable having unchanged electrical characteristics even after severe bending such as might be encountered under the worst conditions of installation. For example, consider a cable whose insulation wall is made up of two types of paper. If the more easily deformed paper is placed on the outside (where the most severe mechanical strains occur during flexing), when the cable is bent back and forth the outer zone of paper will pull away from the inner zone, and an annular gap will develop at the junction of the two types of paper. Obviously if the stronger paper is placed in the outside, there will be no tendency of the two structures to pull apart after severe bending. Mr. Del Mar's construction places the stronger paper on the outside.

The author's contention that the paper tapes of a normal cable are stretched and given a permanent set when the cable is loaded heavily receives support from figure 4. Here is shown the radial compactness of a new solid cable as measured by a Cenco Compactness Tester. The lower curve shows the greatly increased looseness of the insulation near the conductor after load-cycle aging (85 degrees centigrade copper, 30 load cycles). Thus in normal cable severe loading does mechanically stretch the insulation wall, the effect being more severe when heavy load is thrown suddenly on a cold cable.

Out of the phenomenon exhibited by figure 4 comes an interesting and important deduction. If a void is present within the zone of insulation near the conductor where load-cycle distortion takes place, which in this case would be within 40 per cent of the thickness of the insulation wall or about 25 tapes, the paper tapes adjacent to the void will receive no support when the stretching takes place. In consequence the void will be transferred, after a series of severe load cycles, from the middle of the insulation wall to the vicinity of the conductor. In this position the void is far more dangerous to cable life. While it is difficult to measure *void transfer* specifically it is a matter of common observation, especially in the older loosely constructed cables, that after a period of severe service a gap developed between conductor and insulation as indicated by wafer analysis. The remedy, of course, is to build an insulation wall that is mechanically uniform to start with and to support it externally as Mr. Del Mar has done in his new construction.

The author conceives that the insulation of a solid-type cable is reversible up to some limiting temperature where permanent "set" takes place. This conception is supported by the work of Hochstadter and Barrat (1927).[1] It is also supported by wafer examination of cable aged by load cycling at maximum copper temperatures of 45 degrees centigrade, 55 degrees centigrade, 65 degrees centigrade, and 85 degrees centigrade. No change in mechanical structure could be observed in the 45-degree centigrade and 55-degree centigrade sample whereas slight changes were noticeable in the 65-degree centigrade samples and the 85-degree centigrade samples showed very marked mechanical distortion of the insulation wall. [AIEE TRANSACTIONS, volume 57, 1938 (March section), pages 149–50].

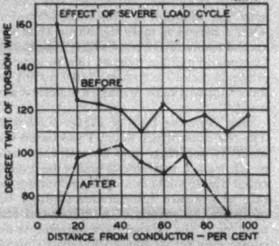

Figure 7

It is my experience that in normal cable of a few years ago, oil and paper expand and contract as one, up to a critical temperature at the conductor of 50 to 60 degrees centigrade ("High Voltage Cable: European and American Practice," minutes, Association of Edison Illuminating Companies, 1936, page 9). This is probably due partly to the elasticity of the paper and partly to the considerable void volume which is present in even the best solid-type cable. (Range of compressible volume at 200 pounds per square inch, probably one-half to three per cent.) It must not be forgotten that very high pressures obtain at the conductor when heavy load is thrown suddenly on cold cable; pressures of 120 pounds per square inch have been measured ("Study of Mechanism of Cable Failure," minutes, Association of Edison Illuminating Companies, 1927) and tapes at the conductor have been reported ruptured as a result.

From the preceding discussion it is evident that high-voltage paper cable insulation requires some external support to prevent the permanent stretching and distorting of the paper layers and the consequent creation of voids of serious radial dimension. This distortion often results from, first, severe bending of the cable during reeling and installation; second, load cycles in excess of some critical temperature, believed to be about 55 or 60 degrees centigrade measured at the conductor; third, the throwing of unusually heavy loads suddenly on a cold cable. In the Titebilt construction the main body of oil-paper insulation is supported by a girdle of high-modulus paper, which serves the double function of mechanical support to the inner layers and of electrical insulation. It would appear, however, that much of the improvement in stability achieved in this manner is due to the elimination of gaps which are prevalent in much "graded" cable, and to the use of the shrinkage properties of the paper to obtain a tight instead of a loose construction by putting the paper with the highest longitudinal shrinkage on the outside instead of on the inside.

REFERENCE

1. EFFECT OF OVERLOAD ON UNDERGROUND CABLES FOR POWER TRANSMISSION, Martin Hochstadter and R. Barrat. *Révue Générale de l'Electricité*, volume 22 (1927), pages 1175–80.

W. A. Del Mar: The main discussion may be divided into two parts, namely:

1. Attempts to explain why the Titebilt principle can't work
2. Attempts to explain why the Titebilt cable does work

In addition to this there were requests for information which I shall endeavor to satisfy before answering these two main subjects of debate.

DATA REQUESTED

Spread of Results in Test Series 1 to 4. The spread of power-factor readings is shown by a typical run of four cables of each of two kinds. In a run of ordinary graded cables, the original power factors had a spread of 0.14 per cent, the average power factor being about 0.9 per cent at 85 degrees centigrade and this spread gradually increased to about 0.24 per cent at the 30th load cycle. Thereafter the spread increased somewhat more rapidly to failure. A typical run of four Titebilt cables showed a spread of original power factors of 0.18, the average power factor being again about 0.9 at 85 degrees centigrade, and gradually increased to 0.32 per cent at 30th load cycle. The subsequent increase was much slower than in the case of the graded cable, until near failure.

Properties of Types S and N Papers

	Type S	Type N
Gurley density, seconds per mil	300	45
SIC impregnated (compound number 7)	3.96	3.60
Dielectric strength, volts per mil	1,800	1,600

Permanent Set. The permanent set of type *S* paper is as follows compared with that of type *N* paper.

Elongation, Per Cent	Per Cent of Permanent Set of Type N
0.9	35
0.8	50
0.7	60
0.6	70
0.5	84

Initial Tightness of Titebilt Taping. Tapes of both types are applied with the same machine tension in all cables reported upon. This tension gives a compactness reading, on a Cenco tester, of about 80 degrees. In this instrument a flat needle is pushed between tapes at a cross section of cable and turned through an angle of 30 degrees by means of a torsion wire. The number of degrees through which the torsion wire must be turned to turn the needle through 30 degrees measures the tightness of taping. The early cables were not taped in an air-conditioned room so that equal machine tensions gave some variability of tightness in the finished cables as shown in figure 9. The later cables, such as that of table I, were taped in an air-conditioned room and show correspondingly uniform tightness in the finished cable.

Negative Ionization in Tests of Table I. The negative ionizations were of the order of half the positive values and occurred when the pressure in the cable was substantially atmospheric.

Pressures, Vacua, and Sheath Expansion in Tests of Table I. Pressures and vacua were measured at the potheads and may not be representative of the cable. The maximum pressure so measured was a little over 100 pounds per square inch and the highest vacuum about 0.6 atmosphere. The lead expansion was measured but the measurements are equally meaningless as the expansion was very little, the measurements of doubtful accuracy by their very nature, and varied along the cable.

Voltage Used for Power-Factor Measurements in Sets 1 to 4. The voltage at which the power-factor measurements were made in connection with the two per cent limit was the AEIC rated voltage of $17{,}000/\sqrt{3}$.

Relative Effects of Titebilt Construction and New Impregnant. The question has been raised, to what extent the stability of the Titebilt cable of table I is due to the Titebilt construction and new impregnant respectively. Tests are under way to estimate this and present indications point to the impregnant as an important element in the long range flatness of the power-factor time curve and the Titebilt construction as the predominating element of its regularity. These tests have now gone over 150 load cycles.

Comparison of Three New Types of Cable. Additional data were requested by Mr. Hickernell to enable him to compare the tests given in AIEE TRANSACTIONS 1940, page 1041 and *Electric Light and Power*, July 1940, page 14, with the Titebilt cable test data. He should have no difficulty in doing so with the data given. The main criterion of stability is the power factor at 60 degrees centigrade which is given at the beginning of the test and once a week thereafter to the end. The power factors at high temperatures are not repeated far enough apart in the standard test to be used for stability evaluation. However, considering the supplemental test, the power factor, at the highest temperature, 115 degrees centigrade, was slightly less after four load cycles at that temperature than it was on the first load cycle due, probably, to a temperature difference that was not observable. The only difficulty Mr. Hickernell will encounter in making a full comparison is the fact that the Titebilt cable was subjected to an additional week of particularly severe load cycles to which the cables described in the publications cited, were not subjected.

Comparative Viscosities of Compounds 7 and 8. From 120 degrees centigrade down to 65 degrees centigrade the viscosities of the two compounds are indistinguishable. Below 65 degrees centigrade they diverge and at 60 degrees centigrade the viscosity of number 8 is about 85 per cent of that of number 7.

Short-Time Dielectric Strength. The plant routine (AEIC) short-time dielectric strength tests have not shown any change since the adoption of Titebilt construction. This, I believe is more significant than any special comparative tests which I might cite. Compound number 8 seems to give some increase in dielectric strength but I do not yet have sufficient data to make a definite statement.

How Were the Data of Figure 1 Derived? The test upon which figure 1 was based was made by applying, from an external source of oil, such a pressure as might be experienced due to voids in a cable and noting the rate of pressure transference through the insulation by means of a differential manometer. The Saybolt viscosimeter is accurate only up to about 700 seconds above which the oil ceases to flow in a stream. Therefore, some other measure of viscosity is required for higher values. Perhaps the Saybolt test might be used, with oil dripping up to 3,500 seconds but the significance of the results would be in doubt. As we were more concerned with the behavior of oil in contact with paper than in contact with metal, we decided to measure the higher viscosities by the time of penetration of oil through paper. The time thus measured was fairly proportional to the Saybolt viscosity over the narrow range that could be measured by both methods. What the relationship may be at higher viscosities we do not know, and, in fact, the question has no meaning. The main point is that the viscosities above 700 seconds were measured by the time of penetration in seconds, multiplying this time by the factor found at viscosities where the methods ran parallel. Theoretically, I could have used the penetration time for the whole scale, and thereby avoided much discussion, but at very low viscosities the time was too short to be measured accurately due both to its dependence on visual observation and the unevenness of the penetration.

The important point about the curve was the existence of a pronounced knee and this was confirmed by tests made on a short length of 500,000-circular-mil cable with 500 mils of insulation sealed at one end and fed with oil from a gravity feed reservoir at the other end. The loss of oil from the reservoir was noted at various oil temperatures, using compound 8 which has about the same viscosity as number 7 from 60 or 65 degrees centigrade up, although less viscous at lower temperatures. These tests showed the same kind of knee at the same viscosity as the earlier tests. The significance of the knee is that when a cable is heated the oil mobility starts low at the bottom right-hand end of the curve exerting great pressure on the inner paper and stretching it. As the knee is passed, the pressure on the paper is released by the oil expanding outwardly by virtue of its increased mobility. The elasticity of the outer paper then comes into play, keeping the inner paper in compression from then on. In cooling this restorative compression continues until the original condition is reached.

Were Comparisons Made Between Round, Sector, and Oval Cables? In reply to Dr. Wiseman's question, no direct comparison has been made between round and sector or oval conductors, as all comparisons have been made between cables of identical geometric design and differing only in the disposition of paper and the kind of impregnant. However, the series 1 to 4 were on round conductors, and a comparative run was made with the sector cable test of table I against an old type cable, i.e., one with ordinary graded insulation and compound 7. It was found that the old type cable started with a 60-degree centigrade power factor of 0.40 per cent, reached 1.37 in four weeks and ended the five weeks test at 1.48 per cent, the intervening values being quite irregular. The test was continued for three weeks more and indicated a very gradual increase which may be compared with the intermediate part of the curve for "ordinary cable" in figure 6. The four weeks rise of 240 per cent (from 0.4 to 1.37) is consistent with the values obtained by Commonwealth Edison Company for standard

12,000-volt cable of 1937 and 1938 vintage, as cited in my paper.

Power-Factor Temperature Data for Cable of Table I. These are as follows:

Temperature, Deg C	Power Factor, Per Cent
20	0.35
40	0.35
60	0.40
70	0.45
80	0.58
100	1.10

Points Raised in Criticism of the Titebilt Principle of Cable

1. *Argument That Load Cycle Tests (Sets 1 to 4) Are Not Indicative of Cable Life.* Mr. Hickernell misquotes me as saying the 1939 Commonwealth Edison Company tests are based on some specific stress. Reference to my paper shows that I said the tests were conducted at "$2^{1}/_{2}$ times operating voltage, corresponding to an average stress of 208 volts per mil," etc. He then goes on to say, in effect, that Halperin and Betzer based their tests on a fixed relation of $2^{1}/_{2}$ to 1 between test voltage and operating voltage regardless of the insulation thickness and therefore had different maximum stresses in different cables. Del Mar, he continues, with a thinner wall of insulation, instead of using the same relation between test and operating voltage, is guided to his test voltage by the maximum stress attained in one out of several Halperin and Betzer cable groups. Why does this particular procedure lead to correlation with the Halperin-Betzer tests? Should not a $2^{1}/_{2}$ ratio have been used, instead?

In my tests, the point at issue was the relative stabilities of cables of equal sizes and insulation thicknesses and in order to tie up with Halperin and Betzer with their invaluable correlation to service conditions, it was necessary to establish a test voltage which would create deterioration at about the same rate, on a smaller cable of lower voltage rating. Deterioration of power factor was found, by our radial power-factor tests, to originate in the regions of calculated maximum stress. It, therefore, seemed most reasonable to adopt a voltage which would give the same calculated maximum stress.

At the time our tests were started, which was long before the publication of the 1936 Halperin and Betzer paper, the only Commonwealth Edison accelerated aging data available were on cables with 750 mils of insulation and the highest maximum stress used which gave satisfactory results was 208 volts per mil. We found to our gratification that our ordinary type cables behaved at 65 degrees centigrade about the same as the best cables shown in Halperin and Betzer's figure 1 for the same temperature and that even at 85 degrees centigrade, the temperature we adopted for our tests, their life was still up to the four-week period regarded as necessary to eliminate questionable cables.

I do not see how we could have used better judgment in formulating our tests. If we had followed Mr. Hickernell's suggestion to use $2^{1}/_{2}$ times the working voltage, the test voltage would have been 24,500 instead of 32,500 and each test, instead of lasting a minimum of 1 month would have lasted a minimum of $5^{1}/_{2}$ months, if the sixth power law is any guide. Such a test would have borne no practical relation to the Halperin and Betzer data.

2. *Argument That There Is Nothing New About Titebilt Cable and That It Has Been Tried Before With Unsatisfactory Results.* Mr. Hickernell gives an interesting list of patents on grading insulation and the impression given is that they have all failed to achieve their purpose and that the idea embodied in Titebilt cable was anticipated by both O'Gorman and T. R. Scott. I took the trouble to look up O'Gorman and found that he mentioned reverse grading only to say that it may occur accidentally due to filtrations of impregnant by cable paper and is to be condemned as being the opposite of his proposed grading system.

T. R. Scott, on the other hand, did make an inverse graded cable that showed promise in the early stages of its development but which ultimately failed due to emphasis being placed on differential oil absorption rather than elastic properties of the paper.

Scott's tests, quoted by Messrs. Hickernell and Wiseman gave the following results.

	Ordinary Grading	Inverse Grading
Max. stress in load cycles calculated on assumption of uniform paper, volts per mil	176	176
Average stress	92	92
No. of cycles to failure—		
Sample 1	36	94
Sample 2	109	96
Power factors at room temperature	Erratic	Consistent
Appearance of insulation after test	Good	Poor

Scott was not seeking power-factor stability, as shown by the absence of power-factor data at operating temperatures. It is of interest, however, to note that his room temperature power factors were very erratic in his graded cable whereas his inverse graded cable except for one point, was quite uniform. One of his graded cables failed at 36 cycles and the other at 109, another sign of nonuniformity. His inverse graded cable was more uniform, failures occurring at 94 and 96 load cycles. Scott's inverse grading was based on the oil capacity of his papers and he paid no particular attention to their mechanical characteristics. Due, however, to a tendency for both oil absorptivity and elastic properties to be related to the degree of hydration of the cellulose, he obtained some slight measure of the characteristic "Titebilt" uniformity, in his inverse graded cable.

Mr. Hickernell seems to have missed the difference between my objective and that of the earlier inventors of graded cable. My aim was power-factor stability; theirs, increased dielectric strength. Whether they attained their objective is not germane to this discussion. The test data presented showed that I attained mine.

3. *If Titebilt Cable Operates on the Principle Claimed, the Action Will Not Be Permanent.* Several speakers, particularly Mr. Atkinson, have suggested that type *S* paper may suffer fatigue in the course of years and lose its modulus and low permanent set, and so the Titebilt action would cease.

It is possible that type *S* paper may suffer fatigue in the course of years, but if so, the much more loosely knit type *N* paper will be even more fatigued and stretched, so that the type *S* paper will not only continue to exert its beneficial influence, but will do so to an increasing extent. That is to say, while under these assumed conditions, the elastic effect might be less than in a new Titebilt cable, it would be much greater than in an aged cable made either with one kind of paper or of two kinds applied as in ordinary grading. For, if the type *S* paper were inside the type *N* paper, the greater fatigue of the type *N* paper would cause it to stretch away from the more stable type *S* paper under it leaving a void space between the two types of paper. That this seems to occur, is shown by the wafers in Mr. Wyatt's discussion.

However, if such creep were to be anticipated, as an important factor, it should be greatest at the start and then fall off, as the paper would be subjected to less stress as it acquired more and more permanent set. Load-cycle tests lasting over a period of six months and including 54 load cycles at 85 degrees centigrade and 62 at 100 degrees centigrade show that no creep occurs even at such high temperatures. Figure 9 shows Cenco tape tightness diagrams for graded and Titebilt cables, otherwise identical in construction, after subjection to the above test at twice operating voltage. It will be noted that the graded cable suffers a loss in tightness throughout whereas in the Titebilt cable the inner layers remain substantially unchanged in tightness, only a few outer layers having suffered. After all, it is the ratio of the moduli that counts, not their absolute values.

Instability of Titebilt Cable Thought to Be Indicated by Imaginary Continuation of the Curve of Figure 6. The imaginary endings *A* and *B* given by Mr. Hickernell to my curve, in his figure 2, have no significance because my curve represents the average of four curves which run together very smoothly for about 50 or 55 load cycles and then diverge, crossing the two per cent line at different points. It is therefore impossible to make a significant average curve above 50 or 55 load cycles and for that reason I stopped the curve at that point. As, however, all the Titebilt cables passed at least 67 load cycles, with an average of 69 before reaching the power-factor limit of two per cent and the graded cables averaged only 30 load cycles, I fail to follow Mr. Hickernell's reasoning that this shows instability of the Titebilt cable.

It Is Questioned How the Permanent Set Can Be Enough to Leave Ionizable Voids and Yet the Stretch, Which Is Several Times as Great, Be Insufficient to Permit Free Flow of Oil. I think that in asking this question Mr. Davis was visualizing a single microscopic tape space in a cable that had expanded with perfect geometric uniformity. That is not what happens, as may be seen by an inspection of cable wafers. Expansion and contraction are no respecters of geometry. A group of tapes will be forced tightly together and their residual gaps, created by permanent set, will be pooled in one layer in which ionization will have full play. Next load cycle this will occur in another place. It is the group closing that virtually shuts off the oil flow and the group openings that permit ionization.

Calculations of Mechanical Stresses in Cables Do Not Support Titebilt Idea. It is claimed by Mr. Greenfield that calculations of mechanical stresses due to oil expansion do not support the Titebilt theory. His own discussion, however, shows how unreliable are such calculations. Moreover, he forgot to include the very important item of residual gas which is by no means negligible in the best of solid-type cables and affords a very considerable cushioning for the expanding oil. My own calculations served as guides for the laboratory work but I lack confidence in their accuracy as representative of the actual complicated conditions in a cable.

All Type S Versus Titebilt. It was suggested that, according to the theory of elastic moduli a cable made of all type *S* paper might be better than one made of two types.

The fact that this is not so is proved by such tests as those described below under "The Oil-Stress Theory." The reason is that the modulus effect cannot come into play unless there is, initially, close and uniform contact of inner layers. This condition cannot be attained with hard, springy, type *S* paper but is ensured by the use of a soft inner paper with low drying shrinkage surrounded by a paper of much higher shrinkage. This ensures that the greater modulus of the outer paper will come into play at an early stage of the oil expansion.

Oil Flow Versus Paper Stretch. The theory upon which the Titebilt cable was designed is not, as several discussers seem to assume that the oil is completely "frozen" in the cable and that all the movement that occurs in load cycles is paper stretching; but that the *deteriorating occurrence* in an ordinary cable is the stretching of the paper and not the outward flow of the oil as hitherto assumed and still maintained by several of the speakers.

Mr. Atkinson made a test to prove that some oil is lost from the insulation when expansion occurs but it was not necessary to make special tests to prove this as we all know it by observation, as pointed out by Mr. Halperin.

The loss, however, is not very great in practice as we find in comparing a new cable with one which has gone through months of severe load cycles. In such cases there is little difference in the amounts of oil between insulation and sheath before and after test.

I am not so much concerned with oil lost by the outer layers of insulation as to make sure that the inner layers are kept free of voids. The oil will contract into its original space, as mercury contracts into a thermometer bulb, if the original space remains unchanged. If, however, the space has been increased by stretching of the paper, the oil cannot fill it by contraction but must be moved in bodily with no force to propel it but the less than one atmosphere due to the partial vacuum formed.

Referring to Mr. Halperin's comparative viscosities, my data indicate that oil-filled cable oil at 30 degrees centigrade has the same viscosity as compound 7 at 120 degrees centigrade, not 80 degrees centigrade.

Mr. Halperin's tests of a Titebilt cable included putting it through three 7-hour heating period load cycles, and one 15-hour heating period load cycle all at a copper temperature of 115 degrees centigrade, and he found the power factor to remain unchanged. As this temperature was near that of impregnation, he concludes that the stability shown by his tests could not have been due to the oil staying in place. True, the oil does not stay in place after it has passed the bend of the viscosity curve and has stretched the paper sufficiently to enable it to flow at its lowered viscosity. My point, is that when the cable cools, the oil will return, provided that the inner layers have not stretched permanently. If they have acquired a permanent set, voids will form and ionization, with its attendant deterioration, will occur. In the Titebilt cable, we have provided means to keep our thermometer bulb, so to speak, to its original dimensions.

That the inner oil in a Titebilt cable contracts into its original habitat after load cycles up to 115 degrees centigrade is shown by the following observation made by Mr. Halperin himself and noted in his report on a test duplicating that of my table I.

> "The impregnation of the fillers and of the conductor insulation was good. There was no sign of deterioration."

If the oil had not stayed in place, would the impregnation have been so good?

EXPLANATIONS SUGGESTED FOR STABILITY OF TITEBILT CABLE

1. *The Oil-Stress Theory.* Messrs. Greenfield, Peterson, Whitehead, and Wiseman suggest that Titebilt cables may owe their quality to the fact that the internal (type *N*) papers are of lower SIC and therefore throw less stress on the oil in the regions of maximum stress. The stability of Titebilt cable is, no doubt, enhanced, due to this feature but if it were the basic explanation of their stability, cables made entirely of type *N* paper should show the best stability and those made entirely of type *S* paper, the least stability. Such is not the case, these two extreme cases showing no difference, whereas the greatest difference is between the ordinary graded and Titebilt which have much less difference in oil stresses. Typical test data are as follows:

Paper	Calculated Max. Stress in Oil	Load Cycles to Reach Two Per Cent (Average of 4)
All type *N*	383	43
All type *S*	348	42
Titebilt	355	69
Ordinary graded	360	30

These figures are based on the following data:

Construction of cable as in sets 1 to 4

Test voltage—32,500 volts

SIC values—type *S* paper—3.96; type *N* paper—3.60 (both impregnated); oil, 2.10

Stresses are figured without increase due to stranding

2. *Shrinkage in Drying.* Mr. Wyatt suggests that Titebilt cable owes its stability in some measure to being built on the principle of a car wheel having a cast-iron core with a heat expanded and shrunk-on steel tire. Type *S* shrinks 20 per cent more than type *N* paper in drying and this shrinkage occurs before impregnation.

I believe that this is a contributory factor in the operation of Titebilt cable, as it is found from inspection of styrene wafers that the strands of such cable are forced tightly together and never show the mild birdgaging, frequently found in other cables. However, the effect of drying a cable is to loosen it and subsequent impregnation does not restore the tightness. The effect of the Titebilt construction is, therefore, not so much to tighten the insulation as to reduce such initial loosening as would normally occur.

Incidentally, the Titebilt principle could not come into full play in a cable having taping applied with irregular stagger and erratic tensions. It is a child of modern taping practice.

3. Titebilt cable owes its stability to the softness of the inner paper which permits it to follow the contour of the conductor more closely than the hard paper ordinarily used at the conductor surface. This is perhaps a contributory factor, but the inferiority of a cable made with all type *N* shows that it is not vital.

4. Titebilt cable owes its stability to the comparatively low oil absorption of its outer paper, thus causing a lessening of the elastic collapse of the outer layers and so keeping the oil passages comparatively open, thereby preventing voids due to stoppage of oil flow.

This is the principle of the Scott cable mentioned in the discussion and may be a contributory factor in the stability of Titebilt cable, but if it were an essential one, a cable made entirely of type *S* paper should be even better, as all the oil passages would suffer less collapse. Tests, however, show that a cable made of all type *S* paper is far inferior in stability to a Titebilt cable.

5. Titebilt cable owes its stability to

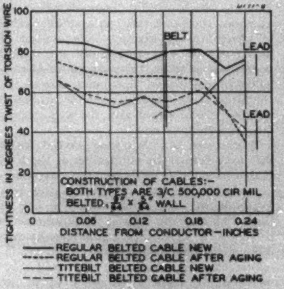

Figure 8. Curves showing radial variation in compactness across insulation wall of cables

Measured across sector base

These cables were aged 54 cycles at 85-degrees-centigrade conductor temperature followed by 62 cycles at 100 degrees centigrade

The rather irregular initial tightness is due to the fact that these cables were made several years ago, before the taping was performed in an air-conditioned atmosphere low permanent set of the outer paper rather than to its high modulus.

The permanent set of type *S* paper is about the same as that of type *N* paper for low elongations, but whereas the permanent set of type *N* increases faster than the elongation, that of type *S* increases less rapidly and, in fact, becomes substantially constant until near failure. This is, undoubtedly a contributory factor in the operation of Titebilt cable but if it were the main factor, an all type *S* cable should be superior, which is not the case.

6. Titebilt cable owes its stability, not to closing of voids, but to pressure put on voids by the outer papers. This suggestion by Mr. Davis seems to imply that the oil in the interior of a Titebilt cable is under sufficient pressure from the belt of relatively impervious paper of higher modulus, as to press into the voids and convert them into regions of high pressure.

If this were an important factor, it should be evident in greater oil pressures at the terminals especially in the vacuum period of the load cycle. We have never seen any evidence of this. However, there may be some local action of this kind which would tend to promote stability.

7. Titebilt cable owes its stability to outer paper preventing stretch of inner paper by virtue of its higher modulus, rather than restoring it to its original condition.

It would be difficult, if not impossible, to differentiate between these two effects. Probably, the higher modulus of the outer paper acts both to restrain stretching of the inner paper and to restore the paper after whatever stretching may occur.

8. Compound 8 owes its stability not so much to its ability to withstand electronic discharges as to either its lower viscosity or that it "fitted the particular paper porosity and cable structure better, irrespective of its resistance to bombardment."

The viscosity of number 8 is somewhat lower than that of number 7 below 60 degrees centigrade, but from there up, there is substantially no difference. Tests were made up to 115 degrees centigrade.

As for compound 8 fitting a particular paper, we find that its superiority holds with papers of such widely different characteristics as type *N* and type *S* used either separately or in combination.

9. There is one factor which is yet under study and which has not yet emerged clearly from a mass of seemingly contradictory data, so that we are not prepared to report it. It ties up with the interesting facts that high-voltage test failures of Titebilt cable frequently originate at the shield rather than at the conductor, as almost invariably happens in graded cables and that in spite of this, the breakdown voltage of Titebilt cable tests, is indistinguishable from that of graded cable.

In conclusion I cannot refrain from noting that there was so little discussion about the new impregnant and of the hitherto unknown relation found between the vacuum cell test of oil stability and the power-factor stability of cable. This surprised me in view of the great interest shown by utility engineers in the stability of cable oils, the subject of an important joint research project which they have sponsored. This research, however, has put its emphasis on oxidation rather than electrical deterioration.

The work on Titebilt cable was performed under the direction of Mr. J. H. Palmer, the details of the load-cycle tests carried out by Mr. Laird McKean, and the work on oil stability by Mr. E. J. Merrell, to all of whom my thanks are due. I also wish to thank the several discussers for their keen analyses of my paper.

Impulse and 60-Cycle Characteristics of Driven Grounds

Discussion and author's closure of paper 41-5 by P. L. Bellaschi, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 123–8.

M. C. Westrate (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper is a contribution on a subject of great interest to those concerned with lightning protection. The inclusion of resistance values measured with a Megger is a valuable addition because of its practical aspect.

Whether the grounds tested are typical is open to question, as it is believed that most companies try to obtain a lower resistance than that obtained with the rods tested. Experience indicates that a resistance of ten ohms or less is desirable for tower footings. The length of the rod of course varies with soil conditions and rods well over 100 feet in length are not uncommon in some areas. Similar tests on longer rods than the ones reported in this paper would also be very interesting.

The data presented by Mr. Bellaschi and plotted in figure 4 of the paper show a decrease in ratio of impulse to 60-cycle resistance with increased current. This agrees with some experience with actual measurements of voltage and current on lightning strokes having much higher current than used in the tests and which showed still lower ratios.

J. Thos. Howard (Tennessee Valley Authority, Chattanooga, Tenn.): Mr. Bellaschi has presented some very interesting data on the resistance characteristics of individual electrodes and a small group of driven grounds with integral values of resistance. It would be of great value to the subject of grounding if the same data were obtained on extensive grounding systems having fractional values of 60-cycle resistance (less than one ohm).

In tables I and III Mr. Bellaschi presents the results of tests at 60 cycles by the voltmeter-ammeter method and by the Megger method. It is to be noted that, in table I, the resistance of both single rods and groups of rods show, with two exceptions, a decrease in the resistance value for increased applied potentials. Table III shows an exceptionally good correlation between measurements obtained by the voltmeter-ammeter method and the Megger method.

During the past several years, the writer has secured data on extensive generating plant and substation grounding systems by the fall-of-potential method, a variation of the voltmeter-ammeter method. Data have been obtained on 11 grounding systems, of which only one showed an integral (more than one ohm) value of resistance. Independent data on the majority of these same grounds have been obtained by the Megger, with this departure from the results shown in table III: that no close correlation exists between the two sets of data, deviations up to 600 per cent being found. In fact, the only case showing any close degree of correlation was noted for the grounding system with the integral value of resistance.

Some of the data have been checked at different values of energizing current into the grounding system. The results bear out the data shown in table I, with one exception. When underground metallic structures connected to the grounding system being investigated were in proximity to the electrodes to which the value of the grounding system was being referred, the resistance value showed an increase for a decreased value of energizing current.

Mr. Bellaschi attributes the decrease in resistance with increase in current to the fact that the increased voltage required to flow more current into a ground electrode breaks down the high-resistance contacts between the more conducting particles of soil. This has not been the case for the extensive grounding systems investigated. These investigations have been made with a potential in the order of either 2,300 or 6,900 volts applied at one end of a transmission line connecting the grounding systems under test, with the other end of the line solidly grounded. The data on the grounding systems at each end of the line have been checked by reversing the source of potential and have been found to check within all practical limits, or approximately ten per cent. From these results it appears that, for extensive grounding systems, at least, the criterion is not the applied voltage but the voltage gradient that individual components of the grounding system can develop.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper gives another proof that the impulse resistance of driven grounds tends to be appreciably lower than the resistance measured by means of Megger and 60-cycle methods. It is shown that in the particular locality tested a very definite trend is indicated in that a decrease of resistance results from an increase in current. However, in the author's tests as well as the other tests mentioned,[1] current waves with relatively slow fronts were used. For instance, from author's figure 3, oscillogram *AX*, the maximum ratio of change of current is approximately 700 amperes per microsecond. I do not have any data on driven grounds with higher rate of current rise, but I believe that the author is somewhat optimistic when he states "that the curve (of figure 4) applies for impulses over a wider range of waves as encountered in the field" and "therefore, the range of currents in figure 4 covers field conditions from a traveling surge to a direct stroke of lightning." It seems to me that in a field where so few test data are available and continuity of service depends so much on low ground resistances, a more pessimistic outlook should prevail. Rates of rise of lightning currents have been measured up to 30,000 amperes per microsecond and lightning current amplitudes up to 200,000 amperes on transmission lines[2] with 130,000 amperes through a single tower, and 25,000 amperes[3] through arresters on distribution circuits. Field experience shows that even higher lightning currents occur on distribution circuits.

For these reasons, it is of greatest importance to know the impedance of grounds for the steep fronts and high rates of current rise actually encountered in the field. Results of tests made on counterpoises[4,5,6] will supply a partial answer to this problem. These tests show:

1. (For a rectangular current wave) that a buried wire has a surge impedance of zero, rises to a high value of the order of 100 to 200 ohms in a fraction of a microsecond after the current wave reaches the counterpoise, and then decreases below the value of resistance measured by alternating voltage means at a rate determined principally by the length of the counterpoise.
2. As the rate of current rise is decreased, the maximum impedance of the counterpoise is decreased.

These results were obtained with currents ranging between 150 and 1,100 amperes amplitude and 750 to 2,500 amperes per microsecond. An essential change in surge impedance variations could not be detected within this range of current variations.

There should exist a marked similarity between a driven ground and a counterpoise, at least for the first half microsecond after the wave reaches the ground rod. Both initially constitute a network of capacitances and inductances and the resistance components come into play only gradually. Therefore, the impulse impedance of a ground rod or system of rods should initially reach a high value to be reduced to the a-c resistance or less. Now, for one short rod, this transition period should, of course, be short, of the order of 0.1 microsecond. However, as the length of the rods increases, and, furthermore, if several rods are connected in parallel by a network of wires of considerable extent, the decrease in impedance will occur at a much slower rate. While this short-time high-impedance value probably is of little importance as far as the sparkover of insulators or other line insulation of high-voltage lines is concerned, it is of considerable importance for the low-voltage lines and distribution circuits. High-voltage insulation requires relatively higher voltages to sparkover at short times than low-voltage insulation (for instance, ratio of sparkover at 0.3 microsecond to critical sparkover for the ten-inch gap is 3.3; for a one-inch gap is 1.64). The approximate spark-over voltages at 0.1 microsecond for insulation for the 1.2, 5, and 8.66 voltage class are 70, 180, and 300 kv respectively. On the basis of a 10,000 amperes impulse, 10,000 amperes per microsecond, surge impedance of 60 ohms, the voltage across the ground system would be 600,000 volts, although the long front resistance of the ground may be of the order of ten ohms or less. Therefore, the insulation spark-over voltages of the lower voltage classes would be definitely exceeded. Tests, made by Baatz,[7] on ground rods of 100 feet length show surge impedance values of 100 to 170 ohms at 0.2 microsecond. This paper also shows the reduction of impedance as the rate of current rise is reduced.

The lowering of ground resistance for impulse currents should, therefore, at the best be considered as an additional safety factor and should not be depended upon until the whole volt-time range of ground rods has been investigated to a much greater extent.

H. M. Towne (General Electric Company, Pittsfield, Mass.): The test results reported in Mr. Bellaschi's paper are a valuable addition to previous work on the behavior of ground resistance to impulse currents. The author's curve, figure 4, showing the ratio of impulse resistance to 60-cycle resistance attending various impulse currents, may be misleading if taken to represent the impulse performance of driven grounds in general. It must be recognized that the range of ground resistance studied with nonoscillatory impulse wave was narrow, from about 22 to 45 ohms at 60-cycle measurement, and hence, while the test points permit one general curve (figure 4) for this range of ground resistance, widely different ratios of impulse resistance to 60-cycle resistance could be expected for the same impulse currents with grounds of say 5 ohms or 100 ohms.

It is interesting that Mr. Bellaschi concurs in the opinion which the writer expressed in 1928, "that the decrease in resistance is probably due to high-resistance contacts between the more conducting particles of soil at, or near, the surface of the electrode, which are bridged over by arcs or sparks when sufficient voltage is applied." If we pursue this theory, then the decrease in ground resistance to impulse current is more basically a function of the soil structure and homogeneity of its conducting elements, and of the actual voltage gradient on the soil, than of the impulse current applied. In other words, it is voltage alone that can cause the arcs or sparks and bridging between conducting particles, and hence for a given character of soil it is expected that a definite applied impulse voltage to the soil close to the ground electrode will produce about the same per cent decrease in resistance of a low-resistance or a high-resistance ground. Hence, current would be significant only in so far as required to produce voltage gradient across the soil.

This can be readily seen from plotting Mr. Bellaschi's data to impulse volt-ampere curves and comparing these to straight-line volt-ampere curves based on the 60-cycle resistance. The writer did this for the author's table IV impulse values of grounds "B and D," "D alone," and "B alone" which had 60-cycle resistances of about 22 ohms, 38 ohms, and 45 ohms respectively. Then taking a given voltage applied, such as 80 kv, the resistance decrease of the 22-ohm ground "BD" was to 0.79, of 38-ohm ground "D alone" was to 0.78, and of 45-ohm ground "B alone" was to 0.80. Thus the decrease of resistance to impulses is practically identical for a given applied voltage to either the 22-, 38-, or 45-ohm grounds.

Using the same volt-ampere curves, and taking a given impulse current through the grounds—such as 3,000 amperes, the reduction ratio for the 22-, 38-, and 45-ohm grounds are 0.84, 0.76, and 0.71 respectively, and are therefore not a direct function of current as might be construed from the author's figure 4.

From this and earlier work, it is believed that the reducing ratio of impulse resistance to 60-cycle resistance of grounds will vary widely, depending on the soil structure and the voltage applied to the ground.

It appears that for the same range of impulse currents used by Mr. Bellaschi, a five-ohm ground would show a resistance reduction to impulses of probably not more than ten per cent (ratio 0.90), whereas a 200-ohm ground might show a resistance reduction to impulses of 70 per cent (ratio 0.30).

Obviously, in conservative grounding practice the indeterminate decrease of resistance to impulse currents should not be depended upon, and grounds should be made sufficiently reliable as determined by the ordinary resistance measurements.

Herbert B. Dwight (Massachusetts Institute of Technology, Cambridge, Mass.): Since ground rods are installed to a large extent with regard to their operation in the case of lightning or other transients, direct measurements of their resistance to transient currents is undoubtedly of much practical value.

Low-frequency measurements of resistance, complete with all dimensions of the ground rods, are not often published and the measurements in this paper offer an opportunity to check up some of the ground rod formulas, as published, among other places, by the writer in reference 3 (AIEE TRANSACTIONS, volume 55, 1936, page 1325).

If the resistance to ground of rod A alone, given in table III, column 1, is substituted in equation 13, reference 3, the resistivity of the ground is $\rho = 14{,}000$ ohms per centimeter cube. From rod B alone, $\rho = 13{,}200$. Substituting the measured resistance to ground of A and B in parallel, 28.0 ohms, in equation 21, reference 3, the value obtained for ρ is 13,300 ohms, which is three per cent less than the average value 13,600 from the two previous measurements. Conversely, using the average value of ρ, 13,600, from the single-rod measurements, the calculated value for A and B in parallel is 28.8 ohms.

Rods C and D have practically the same resistance singly as when in parallel. This fact does not detract from the value of the low-frequency and transient measurements made on them when they are in parallel. Using their measured parallel resistance to ground in equation 21, reference 3, the value obtained for ρ is 15,300 ohms per centimeter cube.

The average of the measured values 13,300 and 15,300 for ground resistivity is 14,300 ohms per centimeter cube. Using this value of ρ with equations 15, 16, 17, and 18 in the manner described for groups of ground rods in the paragraphs following equation 20a, reference 3, the resistance to ground of the group of four rods is found to be 19.6 ohms which is ten per cent greater than the measured value 17.8 ohms given in table III.

In view of the variations in ground resistivity which are known to exist over short distances in almost any location, the above comparisons between calculated and measured values can be considered to be good checks. They are in substantial agreement with those given by Mr. Bellaschi.

If there is a large number of rods in a group, the loss in conductivity per rod given by the formulas and curves of reference 3 should be allowed for in designing an installation of ground rods. Unless wide spacings between the rods are used, the loss in low-frequency conductivity per rod may be surprisingly great.

When a comparatively large number of ground rods are installed, such as 25 or more, a small 60-cycle resistance is obtained by using wide spacing such as 25 feet between the rods, making the extent of the group 100 feet or more. This large distance may decrease the value of the protection as regards transient currents. The distance is particularly large if a single row of ground rods is used instead of a group. At some time in the future, an investigation of the appropriate spacing in large groups of ground rods, made with an impulse generator, showing comparisons between the results with wide spacings and close spacings, should be of value.

P. L. Bellaschi: First I want to thank all who have discussed the paper for their contributions and suggestions. May I state again that one of the objectives of the paper is to fill in the present existing gap in our fundamental knowledge on grounds. Another aim is to stir up interest and develop concerted activity in this important field of work.

In reply to Mr. Westrate, we have made tests on a $^5/_8$-inch steel rod driven 29 feet into the ground (largely clay). The Megger resistance is 12 ohms. At an impulse current of 15,500 amperes, the ratio of impulse to 60-cycle resistance is 0.50. Judging from field observations and discussions, the individual driven rods tested are rather typical, particularly in distribution practice. Should a ten-ohm ground installation be required however, and provided this can be justified economically, the individual rods naturally would be combined in multiple or driven deeper or treated. Mr. Westrate mentions field experience with higher lightning currents than used in the tests. These showed still lower ratios. This is expected. For instance, from a consideration of the gradients developed in the soil, the curve in figure 4 extrapolated would indicate a ratio of 0.30 at 50,000 amperes. A major breakdown in the earth may occur before this current is reached, resulting in an even lower ratio. From tests made, the same rod driven in sand would have a ratio of 0.20 to 10,000 amperes.

The good agreement between the voltmeter-ammeter and the Megger methods in table III was more or less anticipated. Considering the principles involved and the problem, the voltmeter-ammeter method or the equivalent method Mr. Howard refers to, is preferred and in fact, necessary in the case of extensive systems having fractional values of 60-cycle resistance. Potentials of 2,300 and 6,900 volts, particularly when applied to extensive grounding systems, are not likely to develop gradient stresses in the soil sufficient to cause breakdown. On the other hand, potentials in the order of 20 kv and less (table IV) when applied to a single driven ground develop gradients sufficient to cause sparking between particles in the soil, with the result that a lowering of the resistance of the driven ground takes place.

Mr. Howard and Professor Dwight suggest impulse tests on extensive grounding systems and on large groups of ground rods. Such systems essentially are networks of individual grounds connected together. In such a case, the effect of leads is an important factor. I fully recognize the value of extending the work reported in the paper.

As Mr. Towne states in his discussion, the gradient stress is a determining factor. In fact, I have shown in the presentation of the paper, that on the basis of a critical gradient (approximately one to two kilovolts per centimeter), the curve form of figure 4 can be determined by calculation with a good degree of approximation. The determining factors can be stated as the product of the current density in the soil at or near the electrode and the resistivity of the soil. Obviously then, the characteristics in figure 4 will vary with the different electrodes and the various kinds of soil. This point is amply emphasized and developed in the paper. Yet from the practical end, it is convenient to report data in such form as given in figure 4.

The paper attacks the problem from the research approach. Until such time as the impulse characteristics of grounds are more comprehensively established, I agree with Mr. Towne and with Mr. Hagenguth that conservative grounding practices should be advocated.

As to the extent lightning currents are simulated in the tests reported in the paper, I believe Mr. Hagenguth takes a somewhat pessimistic view. It would take this discussion too far afield to review the characteristics of lightning currents, established from the various field investigations to this day. It will suffice to mention that direct measurements (cathode-ray oscillograms) of lightning strokes reported to the CIGRE in 1937 by Messrs. Stekolnikov and Valeev and similar records by Mr. McEachron (*Electric World*, February 10, 1940, page 58) indicate fronts ranging from two to ten microseconds with an average of six microseconds for the eight records. The crest values range from 14,000 to 31,000 amperes. Similar front values were obtained by Professor Norinder. The maximum lightning stroke current in a single tower reported so far is at 135,000 amperes. Considering that the current of the stroke frequently reached ground through several paths—in the case of a tower through the four legs—it is apparent that the tests in figure 4 cover field conditions from a traveling wave to a direct stroke of lightning. There is no sweeping statement made that the more rare but possible severe conditions are necessarily approached. This is a matter for further future studies.

Theoretically it would be desirable to investigate the characteristics of grounds with a rectangular wave front. In most cases, the time constant due to the connecting leads and other inductive effects is such that from an impulse standpoint, it is hardly necessary, even theoretically, to go to such extremes. I appreciate the value of a broad approach in this work. Yet at the same time practical and fundamental considerations indicate that a very fruitful and practical field remains to be explored first with the impulse currents employed in the tests. In some of the tests, the analysis of the oscillograms was extended down to two microseconds.

The charts and formulas Professor Dwight has presented in his analytical treatment on grounds are helpful for estimating purposes, particularly in determining the reduction in resistance expected for the various combinations of the grounds in parallel. However, when it comes to calculating generally the resistance of grounds directly from formulas, I am inclined to counsel caution at this stage, for the reason that our understanding of the resistivity of soils, the factors which affect the resistivity, and the various heterogeneity of conditions in the soil, etc., are still matters that lie at the threshold of a more complete knowledge on grounds.

Minimum Insulation Level for Lightning Protection of Medium-Voltage Lines

Discussion and author's closure of paper 41-14 by H. N. Ekvall, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 128–32.

Eric T. B. Gross (College of the City of New York, N. Y.): There is no doubt that the work in renovating overhead lines has brought about considerable success. After improving the lines over a period of six years, the number of troubles has been reduced by 75 per cent and 62 per cent for the 13-kv and 33-kv systems respectively. It is always good practice to take precautionary measures against any possible trouble that may arise. Dr. Waldorf has very clearly pointed out[1] that there is a fundamental difference between (1) preventive lightning protection and (2) remedial measures, designed to minimize the effect of power arcs following flashovers. As engineers, we should never forget to consider both aspects of the problem and apply all possible means for improvement. I certainly recommend the application of preventive lightning protection, and the work described by Mr. Ekvall belongs in this group. However, it seems to me that the application of resonant neutral grounding (earth-fault coils) would have, in this case, brought at least the same, and very likely a considerably higher, percentage in the reduction of troubles. The reduction in troubles would have come immediately after the installation of earth-fault coils. The cost of these coils would have been comparatively small since the coils must carry only about 10 amperes and 90 amperes for the 13-kv and 33-kv networks respectively. This opinion is based on 15 years practical experience (in Continental Europe and England) in the development and application of resonant grounding.

I have good reason to believe that most of the three wire systems in this country (both overhead line and underground cable systems) with voltages up to 66,000 volts, can be operated with resonant grounding. The only restrictions are that the transformers are sufficiently insulated and that autotransformers are not used for connection to a system with a considerably different voltage. Other apparent difficulties, for example unbalanced charging currents to ground, can in most cases be easily overcome, and also the ground-fault relay problem has its simple solutions.

I want to stress that both preventive and remedial measures should be used, but it is sometimes advantageous to begin with the remedial measures, as they may be more economical and are much quicker to achieve. After all, we are trying to reduce the number of outages and to improve the security of the supply of electric power.

REFERENCE

1. EXPERIENCE WITH PREVENTIVE LIGHTNING PROTECTION ON TRANSMISSION LINES, S. K. Waldorf. AIEE TRANSACTIONS, volume 60, 1941 (June section), pages 249–54.

E. W. Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. The workmanlike survey carried out by Mr. Ekvall and the careful application of the data found have resulted in much improved performance of his lines. This illustrates the practical benefits to be secured from the combination of experience and theory, and the strengthening of the weaker insulations in a system. This paper should be a valuable guide in the design of new lines or the rehabilitation of old ones.

2. In general terms it might be said that good results have been achieved by raising the insulation level of the 33-kv lines to the equivalent of a normal 110-kv circuit.

3. This increase in insulation and removal of low flashover points puts more severe duty on the protective devices in the stations. It is of interest to note that Mr. Ekvall has found no increase in lightning troubles in the stations in spite of this.

4. Additional data on the locations and causes of those interruptions that still occur would be of interest. Perhaps application of protective devices at vulnerable points would improve the performance still more. For instance, the use of protector tubes on pole-top switches has avoided flashovers and interruptions without necessitating increase in switch insulation. Switches are generally vulnerable because when open they are surge reflection points.

5. Experience indicates that even better performance of lines can be obtained by the use of protector tubes. Nevertheless, the improvement in operation obtained by Mr. Ekvall by merely increasing the insulation level is considerable, and whether or not his method or the use of tubes is preferable is largely a question of economics.

F. E. Andrews (Public Service Company of Northern Illinois, Chicago, Ill.): Mr. Ekvall's paper is a distinct contribution to the knowledge and technique of the subject of preventing power-line interruptions caused by lightning.

This discussion will be based on experience with five lines of the Public Service Company of Northern Illinois operating at approximately 34 kv, with grounded neutral, over periods from one to three years.

One point about the method which we question, is the use of wet arc-over distance in determining the length insulation path over porcelain. It would seem that the length of arc path would correspond more nearly to the dry arc-over distance, and we have used this in our data. This difference however does not affect the results materially.

A limited amount of data, from which values similar to those given by Mr. Ekvall's curves can be determined, are available from five single-circuit lines totaling in length about 32 miles, covering 68 mile-years of operation. These data cover construction of both high- and low-ridge pin types of about 3.1 and 1.6 inches per kilovolt phase to phase respectively. The faults have in general been phase to phase or three phase, but in some of the cases the arc scars also indicated a coincident phase-to-ground path, of the same or greater kilovolts per inch. The data, together with values from Mr. Ekvall's curves for comparison follows:

	High-Ridge Pin Construction	Low-Ridge Pin Construction
Miles of line	22.5	9.7
Mile-years of operation	39.2	29.2
Single-circuit structure years of operation	1,093	1,338
Inches per kv phase to phase	3.1	1.6
Power arc faults per 100 structures per year	1.2	0.45
From Ekvall 33-kv curve, faults per 100 structures per year for 3.1 and 1.6 inches per kv, respectively	0.4	0.8
Faults per 100 miles per year	33.2	20.6
1940 average results of all lines in operating division from which above data were obtained, miles of line	44.3	30.7
Faults per 100 miles per year	18.0	19.5

It will be noted that the rate of faults varies widely and inconsistently from the author's curve. In one case our fault rate is three times as high as in Philadelphia, and in the other case about half as great. The lack of agreement of results should not be taken as discrediting Mr. Ekvall's work in any way. This lack of agreement should be considered as an indication of the complexity of the problem and of the need for methods of taking account of such other factors as recovery voltage and those mentioned in the paper, which undoubtedly have great influence on the formation and maintenance of power follow arcs. It also indicates the impracticability of drawing conclusions on this problem from a small number of lines and small amount of data.

One factor which might be responsible for some variation in results in terms of faults per 100 structures, is difference in span lengths. It would seem that the number of ligntning faults would be more directly a function of length of line than number of structures. If this is the case a higher rate per 100 structures would be expected for a line with fewer structures per mile.

It would be interesting to know if Mr. Ekvall in his work found wide divergence from the averages, in the case of individual lines, which might be comparable to the seemingly inconsistent results which we have obtained.

On account of mixtures of old, new, and revised construction in our lines, it has been very difficult to obtain satisfactory comparative data on a year mileage basis. Nevertheless, major reductions in line outage rates are known to have occurred in comparison with the former construction having values of 1.2 inches per kilovolt phase to phase and 0.9 inch per kilovolt phase to ground. Also paralleling Mr. Ekvall's experience, poles having the improved construction have been found splintered by lightning, without any evidence of power arc faults.

It is hoped that others may also contribute data from their systems which in the aggregate may provide a basis for determination of insulation strength values correlated with power arc formation, for general application.

Hollis K. Sels (Public Service Electric and Gas Company, Newark, N. J.): At the winter convention in New York last year, Mr. Ekvall, in discussing a paper on lightning protection of wood-pole lines by Mr. Gothberg and myself, stated "It appears, therefore, that much of the benefit of line performance probably comes from the increased insulation and that a small improvement may come by addition of the protector tubes." I am pleased to have the opportunity of discussing Mr. Ekvall's interesting contribution to the art of improving the protection to wood-pole lines and I hope that my comments may give further enlightenment. Last year we replied to Mr. Ekvall's comments as follows, "Generally speaking, we think that Mr. Ekvall is getting his protection in the deionizing action of the wood as indicated by the splintering so that the economics of his applying tubes depends upon the damage he is experiencing" and I might now add, the further reduction in line interruptions which are desired. In the light of the data which Mr. Ekvall now submits and the additional experience which we have had I see no reason to change our conclusions.

It is appreciated that Mr. Ekvall's data are empirical and that investigations under controlled laboratory conditions would be of considerable value. In fact, such data were presented by A. S. Brookes, R. N. Southgate, and E. R. Whitehead in a paper entitled, "Impulse and Dynamic Flashover Studies of 26 Kv Wood Pole Transmission Constructions" in January 1933 (AIEE TRANSACTIONS, volume 52, 1933, pages 494–501). The paper presented data that closely check Mr. Ekvall's empirical data, that is, at least two inches per kilovolt of insulation are required as a minimum and that I quote from Mr. Ekvall's paper "For the 33-kv system there appears to be no practical value of insulation which will entirely prevent power arc trouble."

Let us look at Philadelphia's performance on 33-kv lines compared to our 26 kv. In 1935, with 36 lightning storm days, Philadelphia had 45 tripouts per 100 circuit miles to our 32 on unprotected lines. In 1940, with 38 lightning storm days, Philadelphia had 17 tripouts per 100 circuit miles to our 1.9 on 345 and 213 miles of protected lines, respectively. This is a 62 per cent reduction compared to a 94 per cent reduction. However, as Mr. Ekvall says, variations in lightning severity in different seasons affect such comparisons and it would be fairer to compare unprotected and protected lines for the same season. Our figures for 1940 per 100 circuit miles are 23.4 for unprotected lines and 1.9 for protected lines, or a reduction of 92 per cent. It would be interesting to have Mr. Ekvall's figures for the remaining 25 per cent or 115 miles of their lines which were unprotected in 1940. I suspect that they have accomplished only about one-half of the benefits which would have been accomplished with the use of protector tubes on the top phase wire. Judging from lines of similar construction, we would expect from 15 to 18 tripouts per 100 miles without protector tubes and we feel that the installation of around 15 tubes per circuit mile is amply justified by the results of 1.9 tripouts per 100 miles or a reduction of approximately 90 per cent.

I wish particularly to call attention to the appreciable increase in cases of pole splintering reported in the paper. We suggest that Philadelphia has raised the insulation level of their line so that certain poles are acting as relief points protecting intermediate poles so that they are experiencing a marked reduction in power arc faults per circuit structure as shown in figure 3, and that the pole splintering in these relief points is principally responsible for the reduction in line interruptions through the deionizing action of the wood. Our suggestion would be that Philadelphia should complete the job by installing protector tubes and realize, first, a further marked reduction in line interruptions and, second, less line maintenance and line outage for that purpose.

H. M. Towne (General Electric Company, Pittsfield, Mass.): Mr. Ekvall's paper reviewing decreased lightning outages of 13.2-kv and 33-kv power lines by appreciable increase of line insulation level is of real interest. While the amount of insulation increase over previous construction is not stated in actual values of 60-cycle or impulse flashover voltage, it would appear that the adopted minimum insulation line to ground is the 13-kv pin insulator plus approximately 23 inches of wood on 13-kv system, and 33-kv insulation plus approximately 44 inches of wood on 33-kv system. Based on published data on impulse flashover of pin insulators in series with wood insulation, the lightning dry flashover level (average of positive and negative $1^1/_2$ by 40 full wave) appears to be of the order of 310-kv and 630-kv crest for the 13-kv and 33-kv lines respectively.

Presumably, the original lines had impulse flashover levels of one-quarter to one-half of these "renovized" flashover levels. Hence, the increase in impulse voltage required to flashover should in itself result in appreciably reduced number of lightning outages. Most authorities believe that lightning voltages from cloud induction are not likely to exceed the order of 500 kv and, therefore, as the impulse flashover level of an exposed line approaches or exceeds the order of 500 kv, there will be a substantial reduction or final elimination of induced lightning flashovers, and the much less probable direct strokes to the line will become the only cause of lightning flashover. It would therefore appear that two factors are present in the substantial reduction of "power arc trouble" and interruptions, which Mr. Ekvall has realized; first, that the "renovized" lines are decidedly less susceptible to lightning voltage sparkover and second, that if and when lightning sparkover does occur the increased arcing distance in "inches per kv" of power voltage tends to prevent development or sustaining of a power arc. Which of these factors is predominant in the over-all reduction of outages may require vigilant observation with particular effort to determine the number of lightning sparkovers of insulation after "renovizing" as compared to before "renovizing." Also, by obtaining the number of lightning sparkovers plus power current which cause interruptions after "renovizing," the relative influence of these factors might be segregated.

It may be found that the "inches per kilovolt" to prevent development or sustaining of a power arc on either 13-kv or 33-kv circuits are influenced by variables at different parts of the system, such as magnitude of available short-circuit currents, system recovery voltage, neutral connections, load current, and, of course, the point on the 60-cycle voltage wave at which the lightning voltage is superimposed.

The notable reductions in system outages already observed from Mr. Ekvall's improved line construction should be of great interest to many utilities dealing with these medium voltage class systems.

J. T. Lusignan, Jr. (Ohio Brass Company, Mansfield, Ohio): In handling the lightning problem on his company's 13- and 33-kv system, the author describes a method of attack which I feel is most clever. The idea of taking field data already available from damaged structures and out of them deriving bench marks for design revisions is obviously a most efficient procedure. I have only a few comments and questions regarding some of the factors he discusses.

He mentions that ". . . . . the arc-over path was considered as being along the surface of the pole or crossarm rather than directly between wires in air." In checking some of the paths between conductors on the structures he illustrates, and comparing them with alternate paths through air, some of our laboratory results described last year in a paper by C. J. Miller and myself ["What Wood May Add to Primary Insulation for Withstanding Lightning" by Joseph T. Lusignan, Jr., and Charles J. Miller, Jr., AIEE Transactions, volume 59, 1940 (September section), page 534] indicate that the surface paths may not always be followed by the flashovers. I am wondering whether the author considered some of the alternate air distances on that basis. I would particularly like to know whether he found any conductor marks in mid-span where some of the diagonal air paths might be unwittingly short.

The author mentions using the "wet arc-over distance" of insulators. I wonder why that was chosen rather than the "dry arc-over distance," or, using the newer phrase, the "striking distance." It seems that the latter would represent the lengths of the flashover and the power follow paths a little better.

The curves plotted in figure 3 are very interesting. I would like to ask whether the grouping of the data points was such that a band could not have been drawn, including within it both the 13-kv and 33-kv sets of data, thereby allowing a possible common "inches per kilovolt" picture. The non-parallelism and crossing of the lines on figure 3 puzzles me.

The author mentions using a relation of two-to-one for the comparative strengths of air and wood insulation paths. Our laboratory results alluded to above, indicate that under average favorable conditions air may only be 20 or 30 per cent better than wood.

The author states that "approximately the same percentage reduction in power arc faults as in line interruptions were obtained." Does he mean "faults to be the detected damaged points on a system and the "interruptions" the switch operations on his log sheets? If so, it is apparent that his data and his conclusions are well founded.

In lengthening insulation paths between phases and to ground, reductions in lightning trouble of course may be the result of reduced initial lightning flashovers due to the greater insulation strengths as well as reduced power follow arcs.

H. N. Ekvall: F. E. Andrews questions the use of wet arc-cover distance in determining the length of arc path over porcelain. Wet arc-over distance was taken because it was thought that under rain conditions the effective arc-over distance would be shortened and therefore the insulators would be somewhat less effective in preventing arc formation than under dry conditions. This was thought to apply particularly in the initial stages of arc formation. However, as indicated by Andrews the difference between wet and dry arc-over distance for the porcelain is small compared to the total length of porcelain and wood in the arc-over path, so that selection of either the dry or wet value would not materially affect the results.

Concerning the inconsistencies and wide variations which are found in comparing Andrews' experience on five lines with data from the curves in figure 3, we agree that it is impractical to draw conclusions from a small number of lines and limited experience. We have found wide divergence from the average values shown on these curves when the number of structures studied was comparatively small. It was only possible to get a consistent trend in results by analyzing the performance of thousands of structures throughout the entire system. In this way we believe we were able to offset to a large extent the localized effect of lightning storms as well as the variable effects of other factors, such as system recovery voltage, magnitude of short-circuit current, circuit tripping time, wind, rain, and others.

It is probably true that the number of lightning faults is more directly a function of length of line than number of structures per mile. However, in our studies span lengths were fairly uniform and therefore comparisons could be made on the basis of faults per 100 structures without introducing any appreciable error. For comparisons with systems having appreciably greater or lesser span lengths than our 33-kv average of 125 feet, it would probably be more accurate to convert our data to faults per mile.

Use of protector tubes on switches as proposed by E. W. Beck has been tried successfully on 13-kv lines, but with some unfavorable results on the 33-kv lines due mainly to the inability of the tubes to clear the heavy follow currents at a number of locations. At present we are attempting to minimize lightning trouble by use of the wood-insulated 33-kv vertical switch shown in figure 5. On the 13-kv lines gang-operated conventional switch units are now being mounted in high-ridge pin configuration and are provided with wood bars in their operating mechanism between phases and between phase and ground.

Eric T. B. Gross has suggested that we install earth-fault coils as a means of reducing line interruptions due to ground faults. We have already investigated use of these coils and have found from experience of others that they are quite effective. However, the method of protection which we have employed minimizes the chances for ground faults and thereby reduces the utility of the earth-fault coils. Our program of renovizing the lines to obtain increased insulation strength has progressed so far now that it appears more economical to complete it than to install coils.

In reply to questions raised by J. T. Lusignan, Jr., our field experience seems to indicate that lightning flashovers generally occur along the wood structure rather than directly between wires in air. A study of twin circuit vertical structures for example showed that even though the air distance between phases was considerably shorter than the path along the arms and pole, there was definite evidence in the form of splintering that the flashover had gone over the wood. It was also found that in going from six-to-eight- and ten-foot arms the rate of power arc trouble decreased, even though the vertical wire spacing remained the same. While burn marks have been observed on the wires near mid-span, there generally has been evidence that the arc traveled along the wires from the structure where it was initiated by lightning flashover. The question regarding use of wet arc-over distance versus dry arc-over distance has been discussed above.

While the data from which the curves in figure 3 were developed could have been plotted to form a band of common inches per kilovolt for the 13- and 33-kv systems, this was not done because the two systems were in different localities and operating under different conditions. Use of the two-to-one relationship for comparative strengths of air and wood insulation paths was considered to be a good approximation based on the meager flashover data available at the start of this investigation in 1935. It is still probably accurate enough for use by the construction forces in relocation of guys. In our analyses "faults" were considered to be the detected damage points on the system, whereas interruptions were the switch operations taken from the log sheets.

We concur with H. K. Sels that use of protector tubes on our ridge pin wire should further reduce line interruptions due to lightning, but are still not certain that sufficient reduction would be obtained to justify their added cost and also whether in later years failure of the tubes themselves may not offset some of the initial gains. Since our 33-kv system neutral is solidly grounded, we would require higher capacity and higher cost tubes than now used on the Public Service Gas and Electric Company 26-kv system having a 75-ohm neutral ground resistance. Also, as mentioned previously, our experience with tubes on our 33-kv system has not been altogether satisfactory. Sels' comparison of the performance of their 26-kv system with our 33-kv system appears to be based on a misinterpretation of our data. Our reported 62 per cent reduction in line interruptions from 1937 to 1940 is for our 33-kv system as a whole and does not apply solely to that part of the system (75 per cent) which has been improved. If the entire system had been improved, then by simple ratio, the reduction in system interruptions would have been 82 per cent. This figure is the one to be compared with the 94 per cent reduction for improved lines with tubes on the 26-kv system. We regret being unable to make comparison by individual lines, since all of our improvement work has been scattered over the entire system. This is the reason for giving our interruption data for the system as a whole and also for making other comparisons on a structure basis rather than by lines.

H. M. Towne indicates that the improvements which we made were such as to decrease the susceptibility to lightning flashover, as well as to reduce the chances for power arcs if and when such flashovers did occur. Actually in renovizing the lines no attempt was made to reduce lightning flashovers, as it was considered impractical to build sufficient insulation into the structures to prevent them. Accordingly, in some instances, the impulse flashover strength to ground was reduced in order to more economically gain greater phase-to-phase arc-over distance. This situation occurred quite frequently where crossarms were lowered two to four feet on the pole to change from flat-top to high-ridge pin configuration. In these cases the reduction in power arc trouble appears to have been due to the greater phase-to-phase arc-over distance minimizing the chances for power arc formation than to any reduction in lightning flashovers. Of course, to prove this would require an accurate knowledge of the actual number of lightning flashovers before and after the improvement. To obtain this information would require use of lightning recording devices on each pole, which for economic reasons was not attempted.

An Experimental Investigation of Subharmonic Currents

Discussion and author's closure of paper 41-11 by J. D. McCrumm, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 533–40.

C. Concordia (General Electric Company, Schenectady, N. Y.): In regard to two of the conclusions drawn in this paper we should like to make the following comments.

Conclusion 2

We believe the statement that "ferroresonance" and "subharmonic oscillation" are totally different and unrelated phenomena is somewhat misleading, since they are really rather closely related. Both depend in more or less the same way on saturation of inductance and on capacitance, and in general the same sort of circuit modifications may be used to guard against either.

Conclusion 6 (2)

While in laboratory tests over a rather large range of circuit parameters and voltage excitation, ferroresonance as defined by the author may give rise to overcurrent conditions in series capacitor circuits; on the other hand, in actual series capacitor installations only the subharmonic phenomena have been encountered. This is presumably because the system voltage is never high enough to produce ferroresonance.

Stephen J. Angello (University of Pennsylvania, Philadelphia, Pa.): Mr. McCrumm is to be congratulated for his careful, extensive experimental work on this nonlinear circuit. I am very much impressed by the range of parameters that Mr. McCrumm's results cover. His diagrams represent many months of labor and they should serve as a valuable guide for theoretical investigators.

During the progress of these experiments work was done at the University of Pennsylvania on the effect of initial conditions on the response in this circuit.

My qualitative observations of the behavior of this circuit substantiate the descriptions of wave form. The term "jittery" subharmonic is very descriptive. These currents seem to have no definite repetitive form. They have been observed to jitter along for ten minutes, and suddenly die out for no apparent reason.

The existence of a "lake" in the "island" is quite certain and seems to me to be a challenge to the theorist.

I will agree with Mr. McCrumm's conclusions in general with one exception, namely, the statement that the wave form of stable subharmonics is independent of boundary conditions. I have found that initial flux linkages in the inductor have an effect on the wave form. A paper on the results of this work is in the process of preparation for publication.

J. D. McCrumm: In reply to Mr. Concordia's comment on conclusion 2, note that this conclusion states that "ferroresonance" and "subharmonic oscillation" are (*a*) totally different phenomena, (*b*) unrelated in behavior. It was not the intention of the author to imply that the two phenomena are totally unrelated, but merely that the response and certain of the underlying causes are unrelated. Indeed, the statement is made in the paper that "the nonlinear characteristic of the inductor is the essential feature of the series circuit that gives rise to both conditions of operation, but beyond that, the underlying causes for the behavior of the resulting current are probably as different as the two phenomena (meaning response) themselves."

The difficulty lies in the attempt to systematize the observed behaviors of this series circuit. While my observations lead to the statement that a large difference exists among these phenomena and the causes, it is a matter of personal feeling as to the degree of this difference, and Mr. Concordia is no doubt justified in feeling that the degree of difference is, perhaps, slight.

I shall be very interested in seeing the results of Mr. Angello's investigation of subharmonic currents. However, my observations still lead to the conclusion that initial conditions are not factors determining the *steady-state* wave form of current in the case of a sustained and stable response. However, it is perfectly true that a so-called switching transient exists before steady state is reached, and that the wave form during this period depends upon the initial conditions.

Development of the Glow-Switch

Discussion of paper 41-70 by R. F. Hays, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 223–6.

Samuel G. Hibben (Director of Applied Lighting, Westinghouse Lamp Division, Bloomfield, N. J.): It becomes increasingly evident that the fluorescent principle will become a permanent and a vital factor in the business of producing light for an indefinite number of years to come. It becomes likewise evident that the business of producing radiant energy constantly grows more complicated.

Even though the development of the incandescent filament lamp has not been simple, yet comparatively the control of many of the factors was rather definite and the engineering was not too involved. Size of source was largely a mechanical problem of bulk and mass. Life was fundamentally a factor of temperature, and efficiency was basically a problem of conserving radiant heat. True, other refinements were important but so long as the applied voltage was reasonably accurate and uniform, the incandescent lamp makers' concern in the normal functioning of their product did not extend back of the lamp socket. The Mazda tungsten filament lamp was generally independent of frequencies, wave forms, position of burning, temperature of surrounding air; was not concerned with noise nor radio interference, and involved to only minor degree the problems of color.

Now almost without warning comes the fluorescent illuminant, requiring the closest co-operation of almost all of the divisions of the electrical fraternity. The proper performance of this new source calls for proper design of several vital accessories. Not only must the lamp tube itself be carefully proportioned and carefully fabricated but of almost equal importance is the character of the ballast, of the starting switch, and the quality of the power that is supplied to the assembly.

D-c usage becomes a difficult problem. Supply voltages higher than the nominal 120-volt range are much easier to adapt than in the case of tungsten filament lamps. Since but one center design of voltage is standardized for each group of ballasts (for example, 118 volts on all nominal 120-volt circuits) it is now increasingly important to guide all medium voltage supply toward the actual 120-volt figure. Wave form and frequency must be considered. Temperatures are matters to be investigated critically. Life is greatly affected by the number of times the fluorescent lamp is turned on and off. The "burned-out" lamp must be promptly replaced.

All in all the fluorescent lamp, like a highly bred animal, is capable of doing a superb job if superbly engineered and intelligently handled. Nevertheless it is not foolproof! It is resourceful, but temperamental. It is not likely to be limited for many years in its variety of shapes, styles, colors, and performances. It is a device that more than ordinarily calls for the closest co-operation between distribution and power supply engineers, transformer designers, contractors, fixture makers—yesand chemists, glass technicians, and many other specialists in addition to those who fabricate the fluorescent lamp itself. This increased complication in the production of light is a challenge to the co-ordinated working of the electrical engineer in all branches. It challenges us to all work closer together and to think further ahead!

Inductive Co-ordination of REA Distribution Systems and Telephone Systems

Discussion and authors' closure of paper 41-19 by K. J. Plucknett, W. T. Smith, and T. A. Taylor, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 586–95.

Ward F. Davidson (Consolidated Edison Company of New York, Inc., New York, N. Y.): The authors are to be commended for giving a clear and informative discussion of a very timely topic. They give further proof, if any were needed, of the value of the co-operative approach to problems of mutual concern to supply and communication systems.

Those familiar with the work of the joint committee on plant co-ordination—Edison Electric Institute and Bell Telephone System, will note certain differences in emphasis and approach from those discussed in the present paper. Under the heading, choice between specific methods in the principles and practices for the inductive co-ordination of supply and signal systems issued by the National Electric Light Association and the Bell Telephone System, December 9, 1922, we read:

> "When specific co-ordinated methods are necessary and there is a choice between specific methods, those which provide the best engineering solution should be adopted."

That has been understood to mean that there is no basis of any preconceived determination as to whether remedial or corrective measures should be applied to the power system or to the communication system or some to each system. Consequently the many reports of the Joint Subcommittee on Development and Research deal with corrective measures in both power systems and communication systems.

The present authors, although recognizing in their introduction, and at the end of the paper, that co-ordinative measures can be applied to the telephone system, do not cover such measures in any detail, and do not give any results of their investigation of the application of such measures. This treatment may lead some readers to the erroneous conclusion that there is little to be done to the rural telephone system in connection with co-ordination. I would like to point out that our experience has shown that there are many co-ordinative measures which are most effective in simplifying the over-all problems which are applicable to the telephone system. These measures are referred to in the references given in this paper and these references should be consulted in the study of any particular problem.

C. W. Frick (General Electric Company, Schenectady, N. Y.): The paper states that rural distribution systems of the type described and metallic telephone circuits can be co-ordinated satisfactorily where several things are done, one of which is restricting the magnitudes of harmonics present in the voltage wave shape of generators. I would like to know what value of TIF the authors have actually found necessary. The only information found in the paper is that in certain individual cases where the machines had a voltage TIF of 25 or less the results were satisfactory, while in a certain case where the TIF was 650 a noise problem was encountered.

About ten years ago co-operative studies were made by the power companies and the manufacturers in order to determine the most reasonable values for the TIF of larger machines. These studies covered the experience in the field with respect to co-ordination, the reduction of harmonics in the wave shape of machines by design, and the taking care of cases of trouble encountered by specific remedial measures. As a result of the studies it appeared that from the over-all standpoint the most economical results for the power and electrical industries would be obtained by a limiting TIF of 50 for machines 10,000 kva and above. For similar reasons the limits set for machines under this rating were 60 for 2,500- to 10,000-kva ratings and 125 for 1,000- to 2,500-kva ratings. These values are given in NELA publication 239 entitled "Generator Wave Shape." No limits were set for machines under 1,000 kva.

The construction of rural systems fed wholly from small machines may require different standards from those adopted for small machines for other purposes. However, it would seem reasonable to expect that if limiting values of TIF of 50 and higher in the case of large machines give satisfactory performance with respect to co-ordination on large systems, they would also give similar results with small machines on small systems provided the same standards are maintained for the power system and the paralleling telephone system as regards co-ordination.

It must be remembered that it was shown in the previous study that the cost of these small machines would be increased in order to meet a limit TIF of 50. The authors' statement that they did not meet such an increase may be attributed to the fact that the situation occurred in only a small number of cases. These machines are widely used for industrial purposes and are required in a variety of sizes, voltages, and speeds. This necessitates different designs requiring many slot combinations which affect the magnitudes of the harmonics and thus the TIF. For example, a machine of a certain kilovolt-ampere and voltage rating and speed might have a much higher TIF than another machine of the same kilovolt-ampere and voltage rating but of a different speed. This is so because the possible slot combinations change with speed kilovolt-amperes and voltage. To meet the requirements which the authors consider as necessary for rural systems would mean the avoidance of certain slot combinations and would require special machines. However, a limit of 50 could probably be met in many but not all cases without too radical changes of design.

While the authors have indicated that they were unable to obtain co-ordination unless the TIF of generators was quite low, the experience of one who has had contact with co-ordination over the past several years seems to show that there are other equally satisfactory co-ordinative measures which can be applied both on the power system and to the telephone system if the values of TIF specified for generators are of the order of the values previously considered for the large generators by the power industry.

C. F. Harding (Purdue University, Lafayette, Ind.): It is considered most timely and appropriate that the earlier studies on such co-ordination should be extended to the rural power lines of which such extensive installations have been made during the past five years. This problem is far more difficult, however, and less likely to have equally satisfactory solution for the following reasons:

1. The types of power line and rural telephone construction are basically more susceptible to creative and receptive disturbances respectively.
2. The apparent necessity for the installation of small or at least cheap generators and distribution transformers introduces harmonic induction not so frequently present in the urban utility systems. However, in many REA systems energy is purchased from the larger public utilities and the advantages of the better generator wave forms are retained.
3. Long distribution lines of the REA, with many single-phase, ground-return feeders and widely varying load factors and power factors, frequently supplying grain elevator motors are not conducive to the satisfactory solution of a single corrective application to meet all needs.

With the low load factor on the individual farm transformer, which emphasizes the importance of low core losses, and the less regulation required for such a supply, it would seem that a special design of transformer with the usual close regulation sacrificed in favor of low core loss might be made available at the low cost necessary to "prove in" on such service. The reduction of the higher harmonics, which are causing most of the difficulty on the rural telephone systems, might also be secured in such designs.

Although the resonant capacitor circuits proposed in this paper may correct inductive interference with telephone lines resulting from higher harmonics for a particular line construction, the addition of branch lines, the introduction of induction regulators, and particularly the more recent use of series capacitors for improved regulation on the very long REA lines are tending to disrupt the improvements of such corrective networks.

The paper seems to stress the possibilities of correction which the REA may undertake rather than those available to the telephone company. From the legal standpoint it is probable that the metallizing of the telephone circuits will be the first important requirement of co-ordination as was the case in the earlier correction of interference between the lines of the large urban power utilities and the telephone systems.

K. J. Plucknett (USDA, Rural Electrification Administration, Washington, D. C.): The installation of many small generators in REA-financed generating plants to supply rural distribution systems has made it necessary to specify low TIF limitations for all generators installed in such plants.

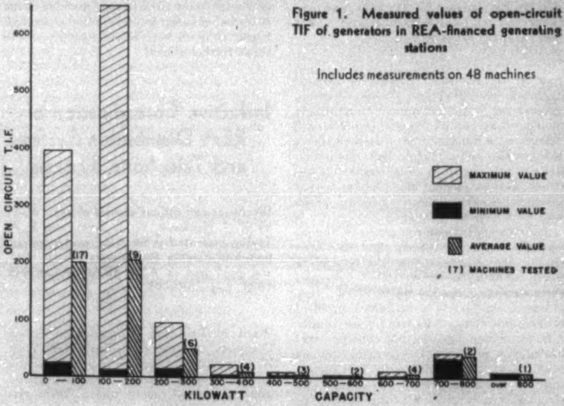

Figure 1. Measured values of open-circuit TIF of generators in REA-financed generating stations

Includes measurements on 48 machines

Figure 1 presents measurements made on 48 machines. It shows that the majority of the machines measured are under 300-kw capacity, and that high values of open-circuit TIF were measured on these machines. In general this chart shows that the TIF decreases as the size of the machines increases.

It is recognized that there are many installations of small generators made in isolated industrial plants, etc., where high TIF is of no consequence, but careful consideration must be given to installations on REA-financed systems to minimize the inductive interference problems resulting from wave shape of generators.

R. D. Evans (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have presented an interesting review of the inductive co-ordination situations involving REA distribution systems. These systems differ from those of other utilities from the co-ordination point of view principally in the greater length of feeders and in the greater use of single-phase extensions of four-wire circuits.

The REA has specified wave-shape requirements for their generators which are relatively severe for machines of their relatively small size. This requirement of low no-load voltage TIF is, no doubt, a logical conclusion of the co-ordination studies involving the REA systems. However, it is not to be inferred that these same requirements should be specified for other generators which are not involved in similar co-ordination problems. It should be appreciated that no substantial improvement in wave shape beyond that of normal commercial machines can be obtained without adverse effects on machine cost or performance. For many years, the co-ordination situation with respect to the smaller synchronous machines has been satisfactory, and in fact machines below 1,000 kva were not even considered in the standardization of TIF levels. Hence for the small machines, TIF levels below those available with normal commercial machines should not be specified unless justified by a particular prospective co-ordination situation. It may be preferable to use filters or other specific measures in the few cases needing attention than to require very low levels on all machines.

In the vast majority of installations the exciting current of distribution transformers has been a negligible factor in inductive co-ordination. In only one co-ordination case that has come to our attention has the exciting current of distribution transformers been the controlling factor and in only a few cases has it been a contributing factor of large importance not considering 8*A*-ringers which are being superseded rapidly. Solution of these cases could be obtained by the application of other measures such as the filters and shunts described in the paper.

In view of the relatively small amount of trouble that has been experienced from the exciting current of distribution transformers it seems to us to be premature to consider setting up a requirement for the exciting-current wave shape. The determination of the wave-shape characteristics of a distribution transformer is a radically different problem from that of determining the wave shape of a synchronous generator. In the case of the generator the wave shape is determined from no-load voltage TIF measurements with the machine disconnected from the system. The measurements are therefore characteristic of the machine. In the case of the distribution-transformer exciting current, however, the measurement of current TIF or the $I{\cdot}T$ product depends not only on the characteristics of the transformer but also on the characteristics of the source as to its harmonic voltages and its impedance at harmonic frequencies. The impedance of the measuring circuit may even be an important factor in the results. We have found that the $I{\cdot}T$ product for one transformer varied over a range of 5.8 to 1 when tested at rated voltage from two different sources, whereas for another unit of about the same rating the $I{\cdot}T$ product varied over a range of only 1.08 to 1 when tested at rated voltage from the same two sources. Consequently, the measurement of the $I{\cdot}T$ product is quite indefinite unless the characteristics of the sources are standardized.

The wave-shape survey conducted by the NELA and Bell system showed that both the balanced and residual $I{\cdot}T$ products for distribution circuits were greater under heavy load than for light load. This indicates that the exciting current is not the controlling factor under heavy load conditions. If provision is made for prospective future loads, the exciting-current problem under initial conditions may be relatively unimportant.

The remedial measures which the authors have applied to solve the field problems encountered with REA systems deserve particular attention. Capacitors, resonant shunts, and filters especially proportioned for the specific case have been used ingeniously in these solutions. This procedure of using inexpensive specific remedial measures appears to provide a better balance in the choice of solutions than would be obtained by an attempt to use general measures alone.

K. J. Plucknett, W. T. Smith, and T. A. Taylor: The discussions offered on this paper have pointed out a number of important considerations in the inductive co-ordination of rural distribution systems and telephone systems. The authors agree with Dr. Davidson that co-ordinative measures in the telephone plant are just as important a consideration in inductive co-ordination with REA lines as with other types of power systems. As pointed out in the paper, no detailed treatment of telephone system measures was included on account of the limitations of space and because experience with these co-ordinative measures had been adequately covered in papers previously presented before the Institute. The co-ordinative measures described in the paper as applicable to rural power systems were tested on an experimental basis. In adopting a final solution for a particular problem all practicable measures were considered, including those available for both the power and telephone systems. Those which represented the best engineering solution were selected. It is interesting to note that, in the cases studied, the final solution usually involved measures in both the power and telephone systems. Thus, it is seen that the co-operative work of the REA and Bell system in fact follows closely the same approach which has been used in the joint work of the private power companies and Bell system for many years.

The discussions of Messrs. Evans and Frick are chiefly concerned with the merits of methods of controlling the inductive influence of rural distribution systems by limitations on the harmonics originating in generators as compared with the treatment of specific cases which may arise where no particular consideration has been given to the limitation of harmonics in their design. There seems to be agreement that these sources may be more important in co-ordination problems involving extensive distribution circuits of the REA type than in problems encountered in the past in connection with urban distribution sytems, or even the less extensive rural systems. Likewise, the number and extent of the REA systems makes it desirable to consider all practicable general approaches to the problem of limiting inductive influence and telephone system susceptiveness in order to minimize the number of specific cases which must be handled in the field. It is with this object in view that the REA has set up wave-shape limitations on generators and is now giving consideration to similar limitations on transformer harmonic exciting currents. The final limits which will ultimately be arrived at by the REA and the manufacturers will depend on the relative costs and the reactions on operating characteristics of incorporating low influence in the fundamental design of generators and transformers as contrasted with the specific treatment of individual situations.

Mr. Frick and Mr. Evans are, of course, correct in saying that limitation of harmonics in generators is much less important where the machines are used in small industrial plants than when they may be employed as the sole source of supply to an extensive rural distribution sytem. However, there have been cases where small rotating machines producing relatively large harmonics have affected the voltage wave shape of power systems from which REA distribution systems were supplied, necessitating the application of remedial measures after detailed field studies.

Mr. Evans points out that few inductive co-ordination problems have been encountered in the past due to transformer exciting currents except in cases where lower-impedance ringer, single-condenser telephone sets were involved. This is undoubtedly true for exposures to urban distribution systems. In such situations the inductive influence is apt to be controlled by harmonics originating in load equipment and the wave-shape survey conducted by the NELA and Bell system and referred to by Mr. Evans was predominantly concerned with urban distribution systems. However, as discussed in detail in reference 2 of the present paper, there are basic differences between urban and extensive rural systems as a result of which harmonic charging and exciting currents tend to control the influence of rural systems. The exciting currents are apt to control the influence where transformers of some of the recent designs which have high harmonic exciting currents are used, and where the harmonics in the voltage of the supply system are small. In the more recent tests it has usually been found that the inductive influence of such rural systems tends to be higher under light load conditions than under heavy load conditions. This is usually due to the combined effects of resonance in the distribution system and the effects of higher exciting currents in the load transformers under light load conditions. As mentioned in the paper the inductive influence of several REA systems has been found to be a maximum when the system was first energized and to decrease as the system loads increased. Another reason for the greater importance of the lower frequency transformer harmonic exciting currents is their tendency to be increased by the application of certain remedial measures which may be used to reduce the effects of harmonic charging currents, as pointed out in the paper.

It is recognized that much remains to be done in working out a satisfactory method of measuring the harmonic exciting currents of distribution transformers. It is expected, however, that agreement on the necessary testing technique can be reached between the REA and the various interested manufacturers.

Professor Harding has mentioned a number of significant points in connection with the co-ordination of rural systems. It is evident from the paper and discussion, however, that the REA is already giving careful consideration to most of the factors mentioned, including limitation of harmonics on their circuits. So far there has been no co-operative experience with the effects of induction regulators and series capacitors but it is felt that their effects will usually not be serious. So far harmonics originating in rotating load equipment connected to the REA systems have not been an important factor in the inductive co-ordination problem. Of course, as the load grows, such problems may arise.

The paper deals primarily with the problem of co-ordination of REA systems and Bell system telephone plant. The legal question of metallizing ground return telephone circuits has never been raised in connection with these studies.

An Electrical Engine Indicator for Measuring Static and Dynamic Pressures

Discussion and authors' closure of paper 40-157 by E. J. Martin, C. E. Grinstead, and R. N. Frawley, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 513–23.

J. E. Hancock (General Electric Company, Schenectady, N. Y.): In the enumeration of the different types of electrical pressure indicators one of the more important types was omitted under the heading "magnetic type indicators." That is, the variable reluctance type in which the position of an armature controls the a-c impedance of an iron core inductance. At first glance this might seem to be the same as the "moving diaphragm" type which indicates rate of change of pressure instead of instantaneous pressure. The use of the variable reluctance type in an a-c bridge circuit will, however, permit the indication of a pressure-time curve directly without the use of complicated high gain amplifiers and integrating circuits such as are required for the moving diaphragm type. Pressure gauges of this type have been built and used in a variety of applications. The frequency response of such a circuit is constant from zero frequency, or static conditions, up to about one-fourth of the carrier frequency used. In many cases the upper limit of the frequencies which can be recorded is determined by the natural frequency of the elastic system used.

The requirement of a high natural frequency of the elastic system is mentioned in the article together with the fact that frequencies up to 6,000 cycles per second may be encountered, but no mention is made of the natural periods obtained in the elastic systems used. Approximate calculations tend to show, moreover, that the natural frequency of the system is of the order of 6,000–8,000 cycles per second.

It is to be noted that figure 15 shows ripples at a frequency of 6,000 cycles per second which might possibly be due to oscillation at the natural frequency of the diaphragm.

The magnetic oscillograph used in these tests shows the possibilities of providing special equipment to meet particular requirements. The instrument described has an optical system of rotating lenses and mirrors which is well suited to the purposes of this investigation. This special optical system, however, prevents the more general use of the oscillograph where it is often desirable to make slower, long strip records.

The need for a frequency response up to about 10,000 cycles per second is mentioned and considered in connection with the indicator and associated electrical equipment. This requirement is, of course, just as important in the recording element as in the indicating element. Thus an oscillograph galvanometer having a natural undamped frequency of 20,000 cycles per second or higher would be required. It would be interesting to know whether this limit was attained, and if so, by what method.

E. J. Martin, C. E. Grinstead, R. N. Frawley: The natural frequency of the high pressure condenser indicator elastic system is well above the frequency suggested by Mr. Hancock. The natural frequency of the diaphragm is 30,000–100,000 cycles per second dependent on the thickness of the diaphragm.

The theory given in our paper concerning the 6,000-cycle wave shown in figure 16 is not speculative. In the last few years, considerable research has been made on the physical nature of detonation in internal combustion engines, as well as the necessary characteristics of instruments for measuring pressures. (See references.)

The frequency response of the galvanometer oscillograph is limited to approximately 1,000 cycles per second. The galvanometer oscillograph is not used where important higher frequency components are encountered.

The Service Factor Rating of Arc-Welding Generators and Transformers

Discussion and authors' closure of paper 41-33 by R. C. Freeman and A. U. Welch, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section) pages 137–41.

J. E. Waugh (General Electric Company, Schenectady, N. Y.): From the point of view of a user of arc-welding equipment, this paper is an excellent step in the right direction toward a more logical method of testing arc-welding generators and transformers.

As indicated by the authors, the present short-time tests of one-half or one hour mean little toward determining what will happen to the equipment on all-day operation. The result has been a general use of equipment of a higher rating than that actually required for a given application.

The choice of a 60 per cent duty cycle is reasonable since probably less than 5 per cent of the present manual welding applications will exceed this figure. It might well be argued that a 60 per cent duty cycle at the rated capacity, under actual average welding conditions of say 1.8 minutes on and 1.2 minutes off, be imposed on the generator or transformer until it has attained a constant temperature. However, if comparable tests indicate that fairly close agreement can be obtained between this method and the proposed testing at 75 per cent of rated current, I am sure that we would all agree to the latter for the sake of greater convenience, testing accuracy, and the closer adherence to existing standards for general purpose motors.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The proposal made in this paper, for an 0.75 service factor rating of arc-welding equipment, seems to me a very desirable step forward. The name-plate amperes will give a single well-understood value of the output delivered during welding operations, while the service factor will give a definite value of continuous heat dissipating capacity that can be accurately checked by test.

In the November 1940 issue of the *BEAMA Journal*, page 76, there is an article entitled "The Rating of Single-Operator Arc-Welding Equipment" by J. W. Bayles, which gives almost identical conclusions, only using a different terminology. In the Bayles paper, the normal ratio of operating to total time, called the "normal intermittency ratio" is suggested to be 0.4, the same as in the French Technical Rules, instead of the 0.6 value recommended by Messrs. Freeman and Welch. It is further suggested that the temperature tests on welding apparatus consist in a continuous run at an output value equal to the square root of the intermittency ratio, which in the British case would be 63.2 per cent, instead of the 75 per cent value here recommended.

In applying this method commercially, it is a question whether to use round numbers for the intermittency ratios or for the service factors. I prefer the latter, since the service factor will appear as a definite part of the rating, while the intermittency ratio will vary for each particular job. For this reason, I suggest that an 0.8 service factor be considered standard, while an 0.7 factor may be used for small equipment or special cases.

K. L. Hansen (Harnischfeger Corporation, Milwaukee, Wis.): As chairman of subcommittee on electric arc-welding apparatus of ASA sectional committee *C*52, I welcome papers of the type presented by Messrs. Freeman and Welch. It has long been recognized that present standards of arc-welding equipment are woefully obsolete and inadequate. This is true of standards pertaining to capacity or temperature rating, and perhaps in greater degree, of standards pertaining to the transient performance, such as current and voltage recovery, etc.

In the early days when arc welding was a repair tool the one-hour rating against a resistance load may have answered the purpose. Now, however, when arc welding has become one of the most important production tools of modern times, it is no longer applicable.

As stated by the authors, production welding is a continuous operation where the loading of the equipment undergoes a more or less regular cycle. Furthermore, it is asserted that a well-ventilated machine with good heat dissipating characteristics may operate continuously at a definite welding load with lower temperature rise than a heavier machine with poor ventilation, although the latter may show lower temperature rise on a one-hour run against a resistance load. This contention is well recognized.

It may be of interest to compare the load cycles given in the paper with those encountered in our own experience. Welding operations in the plant of the Harnischfeger Corporation range from long straight seams on crane girders to welding of small subassemblies requiring considerable positioning between relatively short welds. The average ratio of arc time to total time on the long seams is 73 per cent, and the average ratio for the entire shop is 53 per cent. The suggestion in the paper of considering 60 per cent on and 40 per cent off as the average load cycle for manual welding appears, therefore, to agree very well with our experience, permitting, as it does, a small margin for intermittent overloads.

The recommendation of substituting a

continuous rms current rating based on a 60 per cent load cycle for the present one hour against a resistance load rating is, therefore, a rational one. It constitutes a definite forward step.

While the proposed change is in the right direction, it is a question whether or not it goes far enough. During actual welding, the current drawn from the generator is not a steady one, but fluctuates continuously as the drops of metal pass across the arc. Furthermore, the inrush current, when the arc is struck, may be several times the average welding current. This becomes an important factor when tacking or making a great number of short welds.

Experience has definitely shown that a machine with good transient characteristics will, other things being equal, show less heating on a given job than a machine with poor transient characteristics. I have in mind an installation where a 400-ampere machine outlasted several times to one a 600-ampere machine with considerably larger current fluctuations. In this instance the inferior ability of the 600-ampere machine to stand up was accentuated by the fact that the application was one in which a great number of short welds were made, thus making the inrush current a big factor. The question is: Should the transient performance also enter into the service factor?

The temperature rise by thermometer on the outside of a coil has always been considered a doubtful criterion of the life expectancy of the coil. Coils differ widely in their ability to conduct heat from the inside to the outside, and therefore in thermal gradients. Temperature rise by resistance is more reliable, but neither tells the whole story. A combination of the two furnishes a better picture of the true conditions. It seems rather obvious that a lower hot-spot correction should be applied when the difference between rise by resistance and rise by thermometer is small than when it is large.

In the welding generators we manufacture are coils which show substantially the same rise by thermometer and by resistance. Even with a temperature of 65 degrees (by thermometer and resistance) one of these coils could reasonably be expected to stand up better than a coil with 50 degrees rise by thermometer and 60 degrees by resistance, in spite of the fact that the latter would meet specifications while the former would not.

R. C. Freeman and A. U. Welch: Mr. Hansen's experience with regard to the percentage of welding duty cycles checks well with the values which we have recorded.

The point regarding the effect of transient characteristics upon welder heating is very interesting. In the case cited, it is pointed out that the special nature of the welding duty may have been, to a considerable extent, responsible for the unusual heating of one unit as compared with the other. It is true that such factors as transient characteristics of generator or transformer, the number of short circuits per second in the welding arc, the steadiness with which the arc is held, and the number of starts will influence heating under actual welding conditions.

Thus, although it is realized that other factors are involved to some extent, the fact that experience has shown that welder heating on an average welding load is not greatly different from that on a resistance load, coupled with the need for a simple standard and a test which may be easily performed and consistently checked at various times and locations, has led to the recommendation that heat runs be made on resistance loads.

Among the various accepted methods of temperature rise measurement, no doubt it might be agreed that the resistance method is the most desirable single method for arc-welder windings. Possibly a combination of resistance and surface measurement might be desirable although even in such a case the rise by resistance will be the more reliable inasmuch as it is independent of the location of the thermometer or the thermocouple.

Variations of Atmospheric Temperature With Altitude in the United States

Discussion and author's closure of paper 41-78 by H. W. Tenney, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 230–2.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In his paper Mr. Tenney has supplied data which should prove very valuable in the application of electrical apparatus at high altitudes. In order to avoid any more calculation than necessary, he has confined his study to average temperatures prevailing at various altitudes. Unfortunately, however, it is not the average temperature value which determines the life of the insulation; nevertheless, it is believed that a knowledge of it will be of assistance. It is now generally recognized that the life of insulation is dependent upon time and temperature, and an approximate quantitative valuation can be made by applying the so-called "eight-degree rule," which states that the life of insulation will be decreased by one-half for every eight-degree temperature increase.

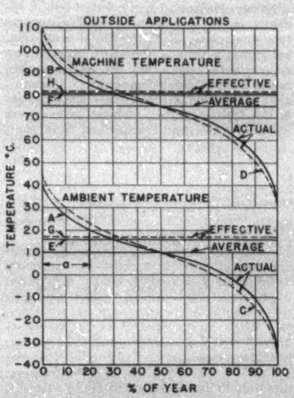

Figure 1

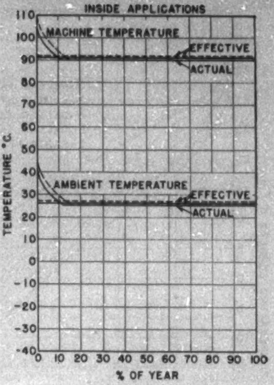

Figure 2

Curve *A* in figure 1 of this discussion is a typical climatic curve showing for a certain locality the number of hours during which a given temperature value is exceeded, the value (*a*) representing the number of hours the temperature exceeds 20 degrees centigrade. By adding to this curve the hot-spot temperature rise of 65 degrees centigrade, curve *B* is obtained. By methods outlined by V. M. Montsinger,[1] it is possible to calculate from curve *B* the constant temperature value (*F*), which in its effect on insulation deterioration is equivalent to that of *B*. By subtracting from the straight line (*F*) the temperature rise of 65 degrees centigrade we obtain line (*E*), which may be considered as giving an effective ambient temperature equivalent to *A*.

Curve *C* represents another climatic time-temperature curve having the same average as *A*, but showing shorter periods for the extreme temperature values. Curve *D* and straight lines *H* and *G* have been derived in the manner previously outlined, and by comparing *E* and *G* it will be seen that the effective or equivalent temperature values vary even though the average temperature is the same in both cases. Complete temperature data such as given in figure 1 are available for but a few localities, and an unreasonable amount of work would of course be required to carry out the calculation indicated in figure 1 for many localities. However, it would seem worth while to make a check of a number of typical localities to make sure that the difference in effective temperatures for different altitudes is at least as great as that between average temperatures. If this fact can be established with reasonable certainty the average values given by Mr. Tenney can be used with safety in applying apparatus at high altitudes, standards for which have been established within the customary low alti-

tude range between sea level and 3,300 feet elevation.

Figure 1 applies of course only to outdoor installations. In figure 2 it has been assumed that indoor temperatures are about the same as outdoor temperatures whenever they are in excess of 25 degrees centigrade; however, they are assumed to be 25 degrees centigrade during the remaining period. This condition can be safely assumed to exist where there is indoor heating for human comfort.

Reference

1. Temperature Limits for Short-Time Overloads for Oil-Insulated Neutral Grounding Devices. V. M. Montsinger. AIEE Transactions, volume 57, 1938 (January section), pages 39–44.

H. W. Tenney: It must be borne clearly in mind that average temperature data for the entire country, or for any major division of the country, cannot necessarily be applied to a particular locality. Climatic conditions vary considerably with the watershed, latitude, season, and peculiar local conditions and only a general study giving average conditions can be presented in a paper of this type.

As Mr. Hellmund has pointed out in his discussion, it is not the average temperature which determines the life of insulation, but rather a time-temperature function, an approximate evaluation of which is obtained by the "eight-degree rule." Figure 3 gives time-temperature curves for six cities in the United States. These curves were prepared from data transcribed from thermograph charts in the office of the United States Weather Bureau. The number of hours per day the temperature was at or above 105, 95, 85, 70, 50, 32, 10, and −10 degrees Fahrenheit were recorded for the years 1932–37, inclusive. From these data the percentage of the time the temperature was at or above these temperatures was calculated and the curves were drawn. The effective temperatures were calculated both for outdoor and indoor conditions and are given in table I. For the indoor calculations it was assumed that the temperature never falls below 25 degrees centigrade.

While the outdoor effective temperatures show a decrease with altitude in the general order of a decrease in average temperature with altitude, for localities of the same general latitude, there is insufficient data from which to establish any definite relationships.

Prime-Mover Speed Governors for Interconnected Systems

Discussion and authors' closure of paper 41-24 by R. J. Caughey and J. B. McClure, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section) pages 147–51.

H. K. Sels (Public Service Electric and Gas Company, Newark, N. J.): Remarks by two of the previous speakers, one by one of the authors and the other by a discusser, challenges my understanding of this problem of governor operation during system short circuits and out-of-step conditions. Mr. McClure dismisses these subjects rather lightly when he says that high-speed relays and circuit breakers do not require improved governor performance. Mr. Marquis also remarks that in a properly designed system there is no problem. I should like to ask what is proper. We in America have some rather large and extensive transmission systems, some of which are modern and some of which are not so modern and I should like to speak a word of caution about dismissing so lightly improved governor performance to handle conditions of electric system stability.

Being somewhat familiar with this end of the problem, I would like to call to the attention of governor designers some of the shortcomings in the protective end of the electrical system. In the first place, as I said before, some of the systems are not so modern and still have a number of relatively low-speed relays and circuit breakers which cannot be economically replaced or rebuilt and at the same time keep our operating expenses to a minimum commensurate with low rates. Much as we like to think of our systems as being ideally designed there are several blank spots in our protective system which are not always economic to provide protection for because faults are considered to be so infrequent. However, faults do occur in these blank spots occasionally and they have to be cleared by slower speed backup relays.

Another limitation to the application of high-speed protection is that while we have several excellent schemes of high-speed protection for phase-to-phase faults no one yet has developed an equivalent scheme except those involving pilot wire or carrier for clearing single-phase faults to ground where neutrals are grounded through some form of impedance. Therefore it is possible for a single phase-to-ground fault to develop into a second phase-to-ground fault at some other point in the system so that a two- or three-phase fault is obtained which appears to individual relays as single-phase faults and result in a rather complicated system disturbance and protective problem.

Finally we also have the possibility of failure of high-speed relays to operate and we are forced to fall back on a second line of defense of slower speed operation.

To sum up this problem, the high-speed protection costs a lot of money both on new installations and particularly on revamping of our older systems and I do not think that improvements in governor performance during system short circuits and out-of-step conditions can be dismissed so lightly. In fact, the designer who brings out a governor having these improvements which might eliminate the necessity for such expensive investments in high-speed relays is going to have a better mousetrap and many people will beat a path to his door.

A. F. Schwendner (Westinghouse Elec. & Mfg. Co., Philadelphia, Pa.): The authors describe and define the necessary, desirable, and nonessential governor characteristics required to operate successfully on an interconnected system. The conclusions reached cover the required governor characteristics in the majority of cases. Only on systems which have an oscillating load where the load changes are a high percentage of the total system load do we find a need for governor characteristics not recommended as necessary in the conclusions. The fast load changes call for governors with a not too high transient incremental regulation and reasonably similar rate of response to minimize load exchange between units or stations. The tie-line load regulator has to be made fast in line with the load changes and the governors will have to follow about the same rate.

The large interconnected systems can operate reasonably well with relatively poor governor performance characteristics. Small interconnected systems, independent generating systems, and systems which have to operate occasionally independent from the interconnection require better governor performance characteristics and can use to advantage additional characteristics which would have very little effect on the large interconnected systems. The authors' conclusions should not be used to cover needed governor performance characteristics on all large generating systems. They describe and define the minimum required governor characteristics for large interconnected systems.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): Our experience on a large interconnected system has, in general, led us to agree with the conclusions reached by Messrs. Caughey and McClure. This is especially true as to the statement in their summary that governing systems on large interconnected networks should have uniform incremental regulation, accurate response for supplementary control, and small dead band. Experience quite definitely shows that less dead band would materially increase the accuracy of response for supplementary control. As to assistance by operating groups in determining improvements or changes necessary in governing systems, we are anxious to co-operate on any tests that would help to determine what the ultimate sensitivity of the governor should be and believe that such tests should be carried out on some of the older vintage machines as well as the newer units. It also seems apparent that, once these factors are determined, more attention should be given to the maintenance of governors and making available a relatively simple means of checking governor performance.

Since the advent of high-speed clearing of faults, we have had no stability troubles. Prior to that time, however, there were cases of trouble and in some cases we have a suspicion that the governor was aggravating the trouble. One particular case was on The Scranton Electric Company system where instability troubles were experienced at the Stanton plant.[1] Occasionally, governor "pumping" resulted and it was believed that the governor contributed to the unstable condition. A series of tests was conducted at Stanton and these led to the conclusion that a properly designed and adjusted governor did not contribute to any system oscillations so long as synchronism is maintained but, when the unit is out of synchronism, the governor attempts to follow the speed changes as the generator slips poles, with the result that the so-called pumping occurs. However, it was definitely shown that this pumping action is a result rather than the cause of a sustained oscillation and may well be expected when the generator and the system are out of step at a certain slip frequency; furthermore, that it will disappear if the generator will pull back into synchronism. It is interesting to note that in this particular case the trouble was solved by the installation of high-speed switching. It is therefore our belief that governors properly adjusted can be eliminated as having any significant effect on system stability on a power system that is properly designed.

1. Governor Performance During System Disturbances, R. C. Buell, R. J. Caughey, E. M. Hunter, and V. M. Marquis. AIEE Transactions, volume 50, 1931, pages 354–69.

J. E. Allen (Pennsylvania Water and Power Company, Baltimore, Md.): The authors of this paper refer to a method of simultaneously recording speed on one axis and governor mechanism movement on the other axis. This discussion is intended to show the manner in which it is done and to point out the possibilities in this method for studying governor performance under normal operating conditions. A new frequency recorder is largely responsible for this accomplishment.

Instead of employing an oscillograph as the reference 8 suggests, a continuous recording frequency meter has been developed having the following characteristics: (1) rectangular co-ordinates, (2) high sensitivity, (3) fast speed of response, and (4) large force available in the pen arm. On account of the last feature it has been possible to add a second pen to the recording arm without impairing the performance of the instrument. This second pen is used in combination with a drum which is rotated by the movement of the operating piston or servomotor. The record obtained from the drum represents a simultaneous plot of frequency versus piston travel and the resulting curve serves as a measure of the governor regulation.

The photograph, figure 1, shows the drum and its relation to the second pen of the frequency recorder. It will be noted that another pen is provided to record piston travel on the same strip chart as the frequency meter. Both the drum and the third pen are actuated from a common string or wire attached to the operating piston. Thus two kinds of records are obtained simultaneously while the unit is regulating on the system: (1) a strip chart showing the relation between frequency and piston travel with respect to time thereby permitting an analysis to be made of dead band and rate of response, and (2) a curve of piston travel versus frequency from which the regulation is obtained.

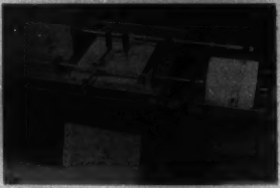

Figure 1. Governor-performance testing equipment

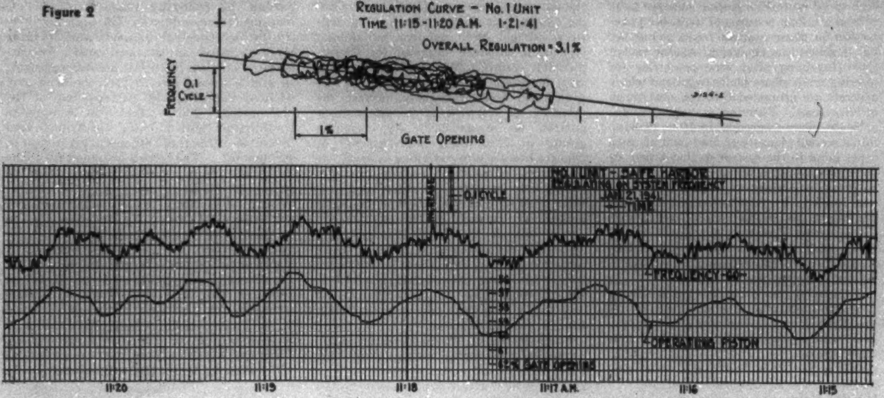
Inherent-speed-droop and servomotor-motion recorders

The important new feature of the equipment as shown in figure 1 is the record on the drum and the method of obtaining the regulation from it. The record consists of characteristic figures resembling an ellipse. When the piston travel is multiplied as shown the figures are greatly elongated and if, after the chart is detached, a line is drawn through the major axis by visual inspection, the slope of the line becomes a measure of the regulation. It is obvious that the regulation thus obtained would be based on the travel of the operating piston or servomotor. If desired, the regulation may be expressed on a kilowatt basis by referring to a test curve of piston travel versus kilowatts output. Since the regulation is obtained while the unit is regulating on the system, the record on the drum consists of a multiplicity of figures superimposed on a common axis. The time required to obtain a sufficient number of figures to establish the slope is a function of the load changes on the system and ordinarily only five to ten minutes are required. The calculations involved in determination of the

Figure 2



slope or regulation are simple and may be done in the field if desired.

The strip chart type of record showing frequency and piston travel with respect to time has been used in the past for governor analysis with gratifying results. However, the possibilities inherent in this simple record have not been fully realized on account of (1) the curved scale charts, and (2) the relatively low sensitivity of the frequency recorders, particularly when used on large interconnected systems where the variations are only about 0.1 cycle. It has been found that the rectangular co-ordinate scale and the high sensitivity as employed in this instrument (0.33 to 1.65 inches per 0.1 cycle) very greatly enhance the value of the strip chart record, making it possible by quick visual inspection to ascertain dead band or rate of response.

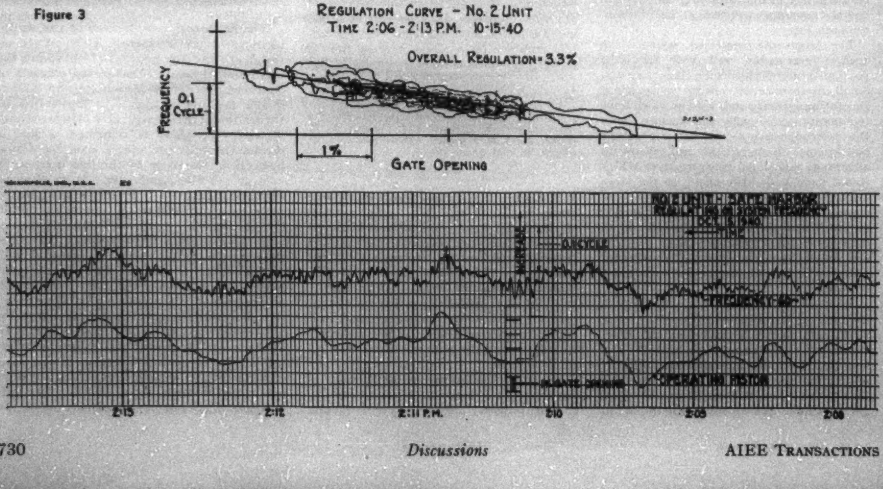
Typical results from this method are given in figures 2 and 3 showing the performance of two hydro governors regulating on the system. The performance of these two units may not at first appear to be very different. However, a closer examination of the strip charts will readily reveal that the governor in figure 2 shows evidence of a larger dead band and a slower rate of response than the one in figure 3. The regulation curves also show that the minor axes of the figures in figure 2 are somewhat greater than those in figure 3. It is believed that the width of the minor axes of the figures on the regulation curve may be used as a relative measure of governor performances. However, caution must be observed in making comparisons since the rate of load or frequency changes may affect the width of the figures due to governor compensation.

The experience acquired from this method of testing has been somewhat limited, but the tests which have been made on both hydro and steam governors have been very encouraging. Since the authors point out that the speed governor is still the backbone of system control, it follows that operating companies should realized the full capabilities of existing governors. Two important needs to this end are: (1) a common basis of analyzing performance, and (2) simple, rugged, and portable testing facilities fully capable of disclosing the high degree of performance inherent in modern governors. It is hoped that the method and equipment briefly described above will prove to be a forward step in meeting both of these needs.

The above method would also appear to be particularly useful as a tool for routine governor maintenance, since the equipment is portable, rugged, and easily operated. The important advantage lies in the ability to determine over-all governor performance while the unit is regulating on the system.

F. Oppenheimer (Pennsylvania Water and Power Company, Baltimore, Md.): I have read all of the papers presented before this group and found in six different places the thought expressed that the per cent speed regulation could or should be increased. In three different places the statement was made that the governor is still the backbone

Figure 3



of system speed regulation. In two places the statement was made that the system frequency should be held within narrow limits to improve certain objectionable conditions.

From these conflicting ideas a complicated conclusion could be drawn as follows: The system frequency should be held within narrower limits, but by increasing the per cent regulation on the governors, as suggested, we prevent them from acting effectively as the backbone of speed control, and we will at the same time have greater frequency variations. A more constructive view of this situation would be to admit that one of the chief purposes of increasing the per cent speed regulation on governors is to hide their shortcomings; therefore correct these, and retain the small per cent regulation or even reduce it, thereby reducing frequency variations, and thus allow the governor to be a real backbone of speed control. In short, I believe that increasing the per cent speed regulation is a step backward.

One of the papers makes the significant statement that "the operation of the governors is usually observed for a period after overhaul." It is probably true that most new governors are observed for a period. A mechanism so complicated requires more than just to be looked at. Suitable instruments should be used to check its performance and when this practice becomes more general, there should be appreciable progress in the speed regulating problem.

R. J. Caughey and **J. B. McClure:** The authors wish to express their appreciation for the discussion which indicates that the subject is a timely one and that many operating groups have contributed to a better appreciation of the problem.

Mr. Marquis, in agreeing with our general conclusions, emphasizes the advantages of small dead band in the governing mechanism in making the response of supplementary control devices more reliable and uniform. Unfortunately we are, as yet, unable to make any concrete suggestions as to what values of dead band should be attained and such values will be arrived at only after more field data have been obtained and analyzed. We would, therefore, be pleased to co-operate with any operating group in making tests on their governors to this end.

Mr. Marquis refers to Scranton tests and these are described in a paper entitled "Governor Performance During System Disturbances" by R. C. Buell, R. J. Caughey, E. M. Hunter, V. M. Marquis, AIEE Transactions, volume 50, 1931, page 354. This reference should appropriately have been included in our bibliography. These tests showed that entrained steam in the machine was sufficient to force the generator out of step regardless of the speed of closing valves and if synchronism were to be maintained the fault duration had to be reduced. Also the pumping phenomenon which is often referred to could be produced only when the machine was running out of step.

Mr. Allen has described a very ingenious method of determining dead band and incremental regulation, and such a method should be useful in making routine tests on the condition of governors during their normal operation.

Mr. Oppenheimer feels that there is some confusion as to what value of regulation is most desirable. In analyzing a record of system frequency there are at least two evident components, first, the slow changing average frequency due to real load changes being accepted by the composite governor characteristics and second, a superimposed fringe which is to a large extent determined by the dead band and regulation. If governors are operated with small regulation, the average frequency will be better and less supplementary correction may be required. However, the frequency fringe will in all probability increase, reflecting itself in more tie-line oscillation and indicating that the margin of stability has been reduced. This suggests that there is an optimum regulation and that variations in frequency may be increased by making the regulation too small as well as by making the regulation too large. Other operating groups have tried various values of regulation and it is interesting to note that they have generally concluded by operating with approximately five per cent over-all regulation, thus obtaining good stability and they have relied on supplementary devices to maintain good average frequency. The suggestion of periodic checks on governing mechanisms is very much in order and will no doubt become a regular routine practice as instruments are made available.

Mr. Sels suggests the desirability of designing a governing mechanism for improved performance during system short circuits and out-of-step conditions. It is generally conceded that the governor performance has very little influence on whether a machine stays in step or loses synchronism during the first swing following a disturbance. This was emphasized by Mr. Marquis in his discussion relative to the Scranton tests. This then brings us to the performance of governors on machines which are operating out of step with the system. Under this condition the machine operates usually at an average overspeed determined by both the regulation of the governor and the induction characteristic of the generator tied to the system. There is also an oscillation in speed at slip frequency and increasing the field has been suggested as a means both of increasing this oscillation, hoping to make it drop down to synchronism, and of increasing the tendency to pull into step when this synchronous speed is reached. Others have found that reducing the speed setting of the governor assists in resynchronizing and some operating companies are now planning to use out-of-step criteria as a means of automatically reducing the speed setting of the governor. It will be interesting to observe the operating experiences of this method. It is common practice to design systems so that the component parts should not lose synchronism during disturbances. Thus it is only when the normal protective equipments fail to function properly that any appreciable benefit from modified governor performance can be realized.

Mr. Schwendner has classified our general conclusions as representing minimum governor requirements for machines connected to a large system. We agree entirely that governor requirements on small systems are different from those on large systems. We believe that the requirements we set forth represent the complete, not minimum, requirements of governing mechanisms for use on the larger systems.

A Power-System Governor Sensitive to Frequency and Load

Discussion of paper 41-15 by Thomas E. Curtis, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 89–92.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): The governing system described by Mr. Curtis is most interesting, and actual operating experience with this type of governor will be awaited with interest.

I believe it should be pointed out, however, that on a large system even a governor with the characteristics outlined by Mr. Curtis will still need supplementary control to properly maintain loading on tie lines.

Power System Governing—the Problem

Discussion and author's closure of paper 41-68 by J. J. Dougherty, A. P. Hayward, A. C. Monteith, and S. B. Griscom, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 547–58.

F. W. Quarles (Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md.): The title of this paper appears to be too inclusive, since it seems to deal almost exclusively with steam turbine governors.

The writer, being of the opinion that the governing of water turbines under transient conditions is a much more difficult task than that of steam turbines, inquires if this condition should not be recognized and a little more consideration be given to this fact in the paper assuming, of course, that the scope of the paper is as wide as the title indicates.

While the statement concerning the impossibility of obtaining two governors having exact duplication of characteristics may be true in the sense that no two devices may be exact duplicates, nevertheless from a practical standpoint the characteristics of two governors of the same design can be made to approach a given standard to a fair degree of satisfaction.

The statement regarding the compression of the governor spring with increase of speed as being usual is considered to be too restricted since there are a large number of governors designed so that an increase of speed extends the governor spring instead of compressing it.

It is suggested that in reference to the complaint about overtravel of speed changer motors because of inertia, this could be limited by use of dynamic braking for d-c motors and solenoid brakes for a-c motors.

Attention is drawn to the fact that the short-time variations of frequency shown on a fast acting frequency meter do not necessarily mean that the changes in governor speed have been of an equivalent amount. This comes about since an a-c generator is not rigidly connected to the bus and load. For the sake of mechanical analogy it may be considered that the generator shaft is connected to the bus and driven load by means of a spring. If the frequency fluctuations originate outside the machine, the spring action together with the rotational inertia of the machine may serve to prevent the speed fluctuations of the generator from being so great. Voltage regulators may even be the source of such indications since a change of excitation changes the phase angle between the generator and the load.

If, on the other hand, machine speed fluctuations originate in the generator unit by reason of faulty governor operation or otherwise, while the unit is carrying load, the frequency meter may not show the full extent of these speed fluctuations.

The spring analogy brings to mind another phase of the governing problem, viz., the oscillating period as related to the units rotational inertia and the spring action. This oscillation, together with that of the weight and spring of a centrifugal weight type governor, constitute the two main oscillating features of such a unit which may result in violent governor action if sizable cyclic variations of the load occur in resonance with a natural period for which there is not a sufficient damping force.

It is observed that in connection with a notation cited from report of company 20 there is the statement that "Experience indicates that, following a sudden drop in frequency, the governor of a machine having low 'steady-state' stability will open up faster than a field adjuster will strengthen the field so that the pull-out torque of the machine may be exceeded." Does not this indicate that it is desirable for high-speed low-inertia machines to have high short-circuit ratios and/or greater field saturation in order to minimize this condition?

The writer is in agreement with the statement as to the need for more refined testing instruments, particularly in regard to obtaining the operating characteristics of a governor under transient conditions. It is considered that the correct basis for such should be machine speed rather than frequency because of the effect of phase-angle variation. If possible, the required instruments should be relatively inexpensive.

In connection with the determination of governor characteristics under transient conditions, Mr. J. E. Allen's discussion of a companion paper "Prime Mover Speed Governors for Interconnected Systems," by R. J. Caughey and J. B. McClure,[1] is quite pertinent. An item of particular interest is the automatic recording or ploting of frequency against turbine valve motion. It is assumed that for an ideal governor, without lag or lost motion, the trace would be only one line. However, the actual trace takes on somewhat the character of hysteresis loops. The difference between the trace with an increasing and that with a decreasing frequency would seem to be the result of various time lags such as that of the turbine speed with respect to terminal or bus frequency; that of the governor weights in reaching equilibrium with the centrifugal force; that of the position of power control valves with respect to governor position; that of the frequency measuring instrument with respect to actual frequency and such lost motions as may occur in the governor or its auxiliary parts and the instrument itself. Here again, the writer recommends the use of turbine speed instead of line frequency unless there is a negligible difference in traces taken under the two conditions.

It may be of interest to mention a device which the writer has used for quite a few years in determining governor regulation. This device is known as a strobometer and consists of a tapered steel cylinder turned by a synchronous motor driven from an electrically maintained 60-cycle tuning fork. A steel wheel carrying an interrupter revolves in contact with the tapered cylinder and can be moved along it by means of a screw. The contactor controls the flashing of a neon lamp which illuminates a symmetrical star on a paper disk attached to the shaft of the turbine. The position of the contactor wheel is determined which causes the star to remain stationary, a suitable scale being provided along the tapered cylinder for reading small deviations of speed from standard. This device is quite accurate but is not suitable for obtaining governor characteristics under actual load since correct values would be dependent upon the alacrity of the observer in obtaining readings.

It is suggested that an optical scheme for obtaining governor performance under transient conditions could very well be used in which a fork timed light would illuminate a suitable figure on the turbine shaft. By taking moving pictures or sufficient still photographs of the figure, together with that of a pointer and scale for valve motion and a clock, suitable data could be obtained. This arrangement should eliminate instrument lag from the problem.

The writer also would like to take this opportunity to strongly urge the unification of governor and control terms to a precise standard.

REFERENCE

1. Discussion by J. E. Allen of R. J. Caughey and J. B. McClure's paper, PRIME MOVER SPEED GOVERNORS FOR INTERCONNECTED SYSTEMS. AIEE TRANSACTIONS, volume 60, 1941, pages 729–30.

R. Rüdenberg (Harvard University, Cambridge, Mass.): It may be of some interest that it is possible to solve with good approximation the problem of the transient interactions between the single parts of a power system, as in the accompanying figure 1, consisting of any number of prime movers of different sizes, with different speed-governor mechanisms and driving different synchronous generators which are interconnected to a common system and loaded, in addition to resistance load, with any number of individual induction motors. The solution[1] which is of remarkable mathematical simplicity, shows that a multitude of oscillations can occur in such a system, the frequency spectrum of which, however, can be divided into three groups, as shown in the accompanying figure 2.

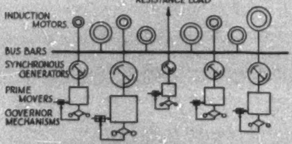


Figure 1. Parts of a power system which suffer transient interactions

Figure 2. Frequencies occurring during transient exchange of power

In general, there develops a single low frequency f_0 which defines a combined oscillation of all the governors together, comprising the inherent properties of their servomotors as well. Furthermore, the inertias of all the induction motors in addition to those of all the synchronous generators enter into this oscillation, which consists of an in-phase movement of all parts of the electric system. The period of these slow frequency swings of the entire system is ordinarily of the order of 10 to 20 seconds.

The next group of frequencies, f_1, determines the more rapid electromagnetic oscillations which occur between each synchronous generator and the entirety of all the other machines in the system. The number of these frequencies equals the number of different synchronous machines. The values of the frequencies are primarily determined by the data of each synchronous machine but are influenced by the electric load of the machines and also slightly by the data of the governor mechanisms. Since the parts of the electric system oscillate in phase opposition, the frequency swings are moderate. The periods, under perfect conditions of the system, are of the order of 0.5 to 2 seconds; under imperfect conditions one or more frequencies may shift into the neighborhood of f_0.

The third and highest group of frequencies, f_2 in the accompanying figure 2 is caused by the inertia effects of the various induction motors, giving oscillations of a period of 0.1 to 0.2 second. These oscillations are damped, however, very quickly by the effect of the rotor slip of each motor.

All these oscillations are excited by every fluctuation of load or by any impact within the system. The subdivision of such impact on all the machines determines the amplitudes of the various oscillations, constituting subsequently the transient load swings within the system. Full-scale ex-

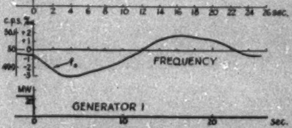

Figure 3. Effect of sudden separation of a generator from an interconnected system

periments with an interconnected system of scores of generators, totaling a power of 800,000 kva and subjected to a sudden impact of 24,000 kw showed initiated load swings and frequency oscillations, as in the accompanying figure 3, which were very close to the computed values.

During such transient oscillations there occur slow and fast exchanges of power between the various parts of the system, temporarily increasing the load on some machines and decreasing it on others, which can be detrimental to good operation. However, tuning conditions can be stated under which all these oscillations reduce to a minimum, thereby yielding the highest possible stability of the entire system. These conditions are: identical natural electromagnetic frequencies of all synchronous machines; identical products of speed droop of the governor with starting time constant of the inertia for all prime movers with their generators; identical closing times of the valve-operating mechanism for every prime mover Although in existing systems it is not always possible to fulfill these conditions completely much can often be done to approach them in order to quiet the operation under adverse circumstances.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): From the answers to the questionnaire in the papers by Messrs. Dougherty, Hayward, Monteith, and Griscom, there does not seem to be any unanimity of opinion as to whether improvements are necessarily advisable on governing systems. This would tend to lead to the conclusion that a great many of us do not know too much about them and points to the desirability of field tests and studies to settle this question. Our experience with the operation of large interconnected systems shows the desirability of proper operation of governors with supplementary control, and that, no matter what was done to improve the governor, in many cases supplementary control in the form of frequency or combined frequency and tie-line control is necessary. Messrs. Dougherty, Hayward, Monteith, and Griscom state that change in steam pressure with change in load is another cause of excessive speed drop Experience certainly bears this out and points to the conclusion that for the ideal system we would really need a boiler that has little or no inertia.

A. P. Hayward: The discussions of this paper indicate a marked interest in the subject of governing, and the committee members responsible for the preparation of this report would like to have these discussions considered as an addition to the report.

One of the discussers has questioned the omission of hydraulic turbine governors from the report. It was realized when this report was being prepared that hydraulic turbine governors have been subjected to rather complete acceptance tests, and in general, have received more attention than steam governors during the initial operation period. The report was limited to a discussion of steam governors as the interest in the governing problem seemed to be based on a desire to learn more about the performance of steam governors.

We would like to summarize some thoughts which have already briefly been mentioned in the report. There is justifiable reason for an investigation of governor performance. The governing system is one of the most important protective devices installed on a prime mover, and probably has not received the attention from the operator that its importance would justify. Methods of determining governor performance and procedure for period tests comparable to similar tests of the electrical protective relays have not been developed on a practical basis.

There are several power systems which have experienced difficulties in maintaining a reasonable speed variation with the existing governors. This condition is the result in general, of supplying steel mill loads. One solution of these difficulties has involved the consideration of governors with low speed regulation and when the speed regulation has approached a value which might indicate the possibility of instability, consideration has been given to the utilization of speed droop compensators. These devices, which provide a means whereby the governor speed regulation can be varied, have considerable merit. They allow units to be operated essentially under base load conditions during full load periods, or when operating with an interconnected system. The governor can then be adjusted for variable load operation during light load periods, or when part of the system may be isolated from the main interconnected system.

A very definite reason for improving governor performance is to assist the electrical system in holding voltage variations to a minimum. The use of shaft exciters with pilot exciters provides an excitation system which produces a voltage variation approaching the third power of the speed change. Large load variations which affect the speed can produce voltage variations which are too fast for satisfactory voltage control. Improvements in the governor performance, which decrease the speed changes, will also decrease the voltage changes and result in more satisfactory overall conditions. Several operators are of the opinion that a lowering of the speed regulation will result in improved speed characteristic without increasing the regulating burden. While it has been shown that there is a limit below which it is safe to reduce the speed regulation of a simple governor, speed droop compensators are available as a means of reducing speed regulation and are operating successfully on the hydraulic units and several large steam units. It seems desirable to further investigate the usefulness of a lower speed regulation before discarding this proposal.

The over-all governor problem involves consideration of the following factors:

The condition of the mechanical speed governor and its ability to respond to speed variations.

The permissible limit of speed variations on the electrical system. This includes a consideration of the frequency variations and its relation to timekeeping, voltage variations resulting from speed changes, and load variations across tie lines.

The relation between governor action and operating conditions in the boiler plant or penstock conditions in the case of hydraulic turbines. The boiler plant should be able to assist system regulation to a considerable degree. Good governor performance does not imply the absence of load variations on the boiler plant.

The degree of perfection required of the governor is an economic balance between governor investment, governor maintenance costs, production costs as affected by governor performance, and expenditures required to realize the operating refinements such as constant frequency, time service, and constant voltage.

Effect of Prime-Mover Speed Governor Characteristics on Power-System Frequency Variations and Tie-Line Power Swings

Discussion and authors' closure of paper 41-23 by C. Concordia, S. B. Crary, and E. E. Parker, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 559–67.

Wm. A. Wilson (Westinghouse Electric and Manufacturing Company, Philadelphia, Pa.): It is gratifying that a paper has been written which further breaks down the demarcation between mechanical and electrical engineering existing at the turbogenerator coupling. Whereas the static relationship of the unit governor to its connected system is well understood, the dynamic unity of the individual machine and the electrically connected system has previously been given almost no quantitative expression.

Complex phenomena are predicted, even within the limitations of the simplifying assumptions employed. Figures 5 and 6 of the paper are examples of such complexity. The extent to which these theoretical results appear in practice will have to be determined experimentally. They will certainly serve as an excellent guide in the establishment of co-operative programs of investigation by manufacturers and operators.

I would like to ask if the differences in character of the system transients as illustrated by the paper's figures 15 and 16 are not less due to the absolute magnitudes of the disturbances than to the relative magnitudes of the frequency disturbances and the governor dead bands? If the systems were completely linear (without dead band) the shape of the transients would be independent of the magnitude of the disturbance. This means that figure 16 which illustrates the effect of an eight per cent load disturbance is probably more characteristic than is figure 15, corresponding to a two per cent load change. In particular, the differences in the system behaviors for cases *A*, *B*, and *C* during the first five seconds after the upset are almost nil in the case of the slight disturbance. For the larger disturbance these differences are striking and suggest an importance of the other system parameters at least as great as of dead band. The authors have described these differences but have, perhaps, not sufficiently emphasized the effects of the many system variables and the location and character of disturbances on the apparent quality of performance of a particular governor.

The method of attack chosen by the

authors has necessitated employing the simplification of using two equal time constants on each governing unit. They have amply justified this procedure, but the importance of a third or even a fourth constant even of small magnitude should not be belittled. Since virtually all governing systems include at least three time constants, the effect of the third on the stability has been calculated by the writer. Figure 1 of the paper has been extended into a third dimension with the addition of another time constant co-ordinate. (The basis for these calculations was a system identical with that considered by the authors except for the addition of a third time constant and a slightly smaller inertia constant—M = 3,800 instead of 4,000.) Actual space curves were constructed using arithmetic scales for the region of small time constant. These constructions were made for T_0=0 and T_0=1. A photograph of these curves is submitted as figure 1 of this discussion. Figure 2 is a rough logarithmic plot in two dimensions with T_0=1 and T_3 as parameter. It is apparent that the addition of a third constant is very significant in the region of small values of T_1 and T_2 and has the effect of largely nullifying the beneficial influence of load damping. In the region of very slow response, there is virtually no effect of a small added constant.

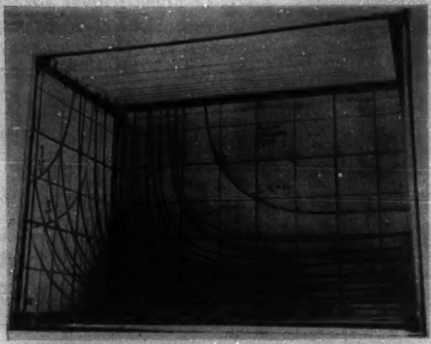

Figure 1. Effect of time lags on governor stability

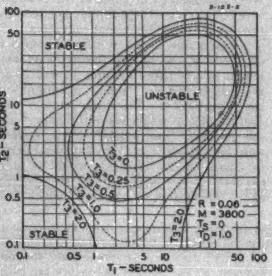

Figure 2. Effect of time lags on governor stability

It may be worth pointing out that the outer region of stability corresponding to large time constants is what makes possible the use of compensators. The minimum time constant permissible for a compensator is dictated by the location of this region on the stability plot for the regulation corresponding to compensation.

I would like to suggest adding to the paper's bibliography the Royal Society paper published August 1937, by Hartree, Porter, Callender, and Stevenson, entitled "Time-Lag in a Control System." This paper includes an exposition of the use of the Differential Analyzer in the solution of differential equations describing control functioning.

H. B. Seeley (Consolidated Edison Company of New York, Inc., New York, N. Y.): Messrs. Concordia, Crary, and Parker have done a very thorough job in exploring the influence of various governor characteristics and system characteristics on frequency stability of systems.

One of the interesting things which their analysis shows is that stable operation is possible for a rather wide range of governor characteristics and system characteristics. It does not appear necessary that each governor in the system should have the same over-all regulation and incremental regulation, the same dead band, and the same speed of response in order to avoid frequency oscillations. This is borne out by the successful operation of many systems having steam and hydro machines of many designs differing considerably in operating characteristics, yet working together in harmony. It would appear that if a majority of governors have small dead band, sufficiently fast response, and large enough incremental regulation, stable operation will result. Even though some units may have poor governor characteristics, the system may be free from sustained frequency oscillations if other governors in the same stations have stable characteristics. Frequency oscillations sometimes appear only when one particular machine in a station is operating by itself.

The authors have pointed out, that, in addition to the governor characteristics, the system characteristics have an important influence on frequency stability. Tests on the Consolidated Edison system illustrate the damping effect produced by load. During recent circuit breaker tests, the test breaker was supplied from a generator which was tied to another station in the system through one high impedance tie circuit. No system load was distributed directly from the generator terminals. The disturbance produced by the breaker test caused this generator to swing with respect to the rest of the system. These swings persisted for 20 to 30 seconds, dying down gradually, which indicated a relatively small damping effect for the generator and tie line alone. On the other hand, in several tests in which system load was distributed directly from the test generator, the swings were very rapidly damped, disappearing almost completely in $1^1/_2$ cycles of swing. This indicates that load distributed at the generator terminals may have a large damping effect on frequency oscillations. It would seem to be a fair conclusion that a system in which a substantial load is distributed directly from each generating station bus would tend to be considerably more stable with respect to frequency oscillations than a system in which some of the stations feed to the load centers through long transmission lines.

Tests made on the Consolidated Edison system did not disclose any swings which could be traced to governor action. Metropolitan systems in general may tend to be unusually stable with respect to frequency oscillations, particularly when:

1. All generating units are steam driven
2. Interstation ties are short, and
3. Load is distributed from each station

When such local systems are tied in with an extended interconnection, they may exert a considerable stabilizing effect on the combined system.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): The work carried out by Messrs. Concordia, Crary, and Parker is a valuable contribution to an understanding of the problem of system governing. It is noted that the authors state that the principal component of the tie-line swings usually has a period of from 0.5 to 5 seconds, while the swing of average frequency may have a period of from 5 to 60 seconds. On the central system of the American Gas and Electric Company, the inherent tie-line load swings have a period of about five seconds and we have measured average swings having a period of 120 seconds. The magnitude of the inherent swings varies roughly from 2,000 to 12,000 kw. The period of the measured inherent swings checks very closely with calculated values.

C. Concordia, S. B. Crary, and E. E. Parker: We are very pleased to note that both Mr. Seeley and Mr. Wilson are in general agreement with the results presented in our paper. Mr. Seeley has mentioned confirming system experience and tests, and in connection with these we are presenting figures 3 and 4 of this discussion.

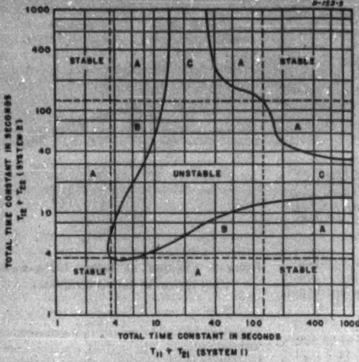

Figure 3. Two machines—effect of solid interconnection with various distributions of governor response

T_s or $T_{d12}=\infty$, $M_1=M_2=4{,}000$, $R_1=R_2=0.06$, $T_{d1}=T_{d2}=1$, $T_{11}=T_{21}$, $T_{12}=T_{22}$

In regions marked stable both machines are stable either separated or tied together

In regions *A* one machine is unstable *if* they are separated

In regions *B* both machines are unstable *if* they are separated

In regions C one machine is unstable if separated and both are unstable if tied together

In region marked unstable both machines are always unstable

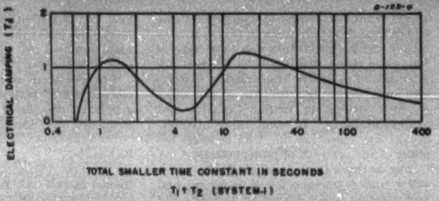

Figure 4. Two interconnected systems with different governor time lags

$M_1=M_2=4{,}000$, $R_1=R_2=0.06$, $T_{12}=T_{22}=16T_{11}=16T_{21}$, $T_S=0.1$
$T_{d12}=0$, $T_{d1}=Td_2=T_d$

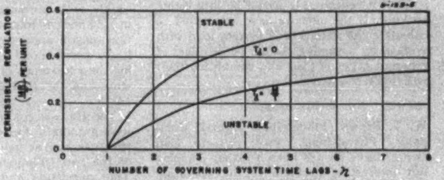

Figure 5. Governing system characteristics—effect of number of time lags on stability

T=total time constant, per unit

Figure 3 of this closure illustrates Mr. Seeley's remarks that even though some units may have poor governor characteristics the whole system may be stable if others have good characteristics, and that good interstation ties are beneficial. This figure shows that a solid tie between two systems one of which is unstable by itself, as in regions (A) of the figure, may be stable as a whole. There is also a small region (B) where the solidly connected system will be stable even if both systems are unstable by themselves.

Figure 4 of this closure is a further illustration of Mr. Seeley's comment that all units need not have identical governor characteristics for successful operation. This figure, with the two parts of the system having widely different speeds of governor response, indicates a somewhat greater degree of stability over the range considered than figure 5 of the paper, in which the governors were alike. However, figure 6 of the paper, for another kind of difference between the governors on the two systems, shows a slight advantage for uniform response. Figure 3 of this closure also indicates some advantage in diversity in governor response. If, for example, the two systems have responses such that they are at the lower right-hand intersection of the dashed lines, the systems are both on the border line of stability when separated but well within the stable region when solidly tied together. On the other hand, if the two systems have equal responses so that they are at the lower left- or upper right-hand intersections of the dashed lines, they are still on the border line of stability when tied together.

Mr. Wilson has mentioned the importance of considering more than two governor time constants, and has made a valuable contribution in this direction. As mentioned in the paper, we may expect the equality of the two time lags to compensate in some measure for their small number. However, it is true that all the results obtained must be considered as only qualitative.

Figure 5 of this discussion is presented in connection with Mr. Wilson's remark that under certain conditions the beneficial effects of load damping may be largely nullified by the addition of a third time constant. It may be seen from the figure that, although the addition of time constants decreases stability, still for any given governing system, load damping is very beneficial. It should be noted that actually a negative regulation is possible with stability with one governor time lag and with load damping, while the figure merely indicates that the regulation may be made as small as desired.

In regard to figures 15 and 16, as Mr. Wilson points out, the relative magnitudes of the frequency disturbance and governor dead band, rather than the absolute magnitude of the disturbance, is the significant factor in determining the character of the system transient. With a given dead band the relative magnitude of the disturbance of course decreases with its absolute magnitude, and we did not think that a 2 per cent load change and a 0.1 per cent dead band were unreasonable values to assume in order to get some idea of the relative performance of the various combinations during small load changes. With either larger load changes or smaller dead bands, the other system characteristics become more important.

We wish to thank both discussers for their contributions.

System Load Swings

Discussion and authors' closure of paper 41-16 by H. A. Bauman, O. W. Manz, Jr., J. E. McCormack, and H. B. Seeley, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 541–7.

Sherwin H. Wright (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The question, "What causes the observed power fluctuations and can they be controlled to advantage?" has been answered by the authors for their particular metropolitan system, and in so doing they may well inspire others to make related investigations. Most systems have noticeable power fluctuations in at least one section of the system. Sometimes a known widely fluctuating load exists and its effect masks the presence of other power fluctuations which in themselves may be unnecessary and controllable. In other cases a power fluctuation of unknown origin is tolerated unless it becomes unduly large. While widespread investigation, of power fluctuations in interconnections and systems, would not prove valuable in every case, it is none the less likely that in some cases profitable results may be obtained.

As the paper brings out, the expression "load swing" does not imply that all of the swings correspond to actual changes in load consumption or power consumption. Rather, as the paper shows in some detail, some of the swings such as the long-time and synchronizing swings are interchanged between generators or generating stations.

While it was found that the long-time

power swings were important largely because of boiler and fuel economy in this system of steam turbine generators, the same type of long-time swing would also be of great importance in extensive transmission systems and interconnections because of the effect of such swings on tie-line capacity and system stability. In some cases of interconnecting lines, the line load is lower because of the presence of power swings.

The authors have mentioned the possibility under emergencies of reducing real and reactive power output by lowering the voltage slightly and in figure 1 have plotted the measured relation for their system. The actual numerical relation of power output and voltage is of interest because of possible application to other systems, and it is also of importance in stability studies where knowledge of the composite load characteristics is necessary. It would be interesting to know if the authors have attempted to calculate the variation of system load with voltage by assuming certain percentages of different types of load and combining their individual characteristics.

W. T. Brown (Philadelphia Electric Company, Philadelphia, Pa.): System load swings have always been a rather complex but interesting problem to the operating engineer. The authors treat the subject from a practical and test standpoint in a very interesting manner. The observation in conclusion 2 that a three per cent change in frequency resulted in no noticeable load change is worthy of some discussion. For instance, numerous tests[1] on the Philadelphia Electric Company system indicated that one per cent change in frequency resulted in about 2.5 per cent change in power load. Thus test observations on two large electric utility systems have resulted in strikingly different conclusions.

The effect of change of frequency upon load apparently would depend greatly upon the nature of the load. Since induction motors and synchronous motors will reduce their speed with reduction in frequency of the supply system, I believe that the mechanical loads that such motors are driving would, in general, require less power. I would expect that railway load (d-c or a-c series motors) would not be appreciably affected by change in frequency. Lighting load, electric range, electric water heater, and similar load would not be affected appreciably by change in frequency. It would therefore appear that the tests made on the Consolidated Edison Company of New York were made in an area whose loads are primarily made up of lighting, railway, and kindred types of load and that the induction motor and synchronous motor load was probably a much smaller percentage of the total load than in the Philadelphia Electric Company system.

While the mechanical loads supplied by induction motors would decrease with reduction in frequency, I could conceive that that the power input might under certain conditions increase. If the transformers and induction motors are normally operated at a relatively high degree of flux saturation due to the operating voltage, then a reduction in frequency could result in an extremely high exciting current. This would result in an increase in power losses in the induction motors, transformers, transmission and distribution systems which may more than offset the decrease in mechanical load supplied by the induction motors, especially those of the smaller sizes.

I believe more extensive tests on various electric utility systems are required before general conclusions of the effect of change of frequency upon load can be drawn safely.

REFERENCE

1. REGULATION OF SYSTEM LOAD AND FREQUENCY, **Herbert Estrada** and **H. A. Dryar**, Philadelphia Electric Company, presented at the ASME annual meeting, Philadelphia, Pa., December 4–8, 1939, and published in ASME *Transactions*, April 1940.

John G. Noest (Brooklyn Edison Company, Brooklyn, N. Y.): The authors state that: "...... short-time load swings do not directly affect station economy unless they couple with automatic control equipment in a manner as to cause hunting of combustion control apparatus." That such coupling is possible and does occur is illustrated by the experience of the Hudson Avenue station of the Brooklyn Edison Company, Inc.

The Hudson Avenue station is equipped with automatic load-frequency control apparatus which actuates the governors of one of the two 160-megawatt turbogenerators. The magnitude and direction of control impulses to the turbine governor depend upon the frequency and tie-line feeder load deviation from standard. This equipment is designed to regulate for average values rather than for instantaneous ones and is therefore not capable of preventing tie-feeder load swings of as short a period as 0.5 to 2 minutes. It does, however, send impulses to the turbine governor which tend to diminish the tie-feeder swings.

The Hudson Avenue station is also equipped with automatic combustion control which actuates fan vanes and boiler dampers, varying their positions in response to steam pressure variations. The master combustion control regulators, as well as the individual regulators for control of fan vanes and dampers are equipped with fluid dashpot types of damping devices by means of which the time constants of response are adjustable.

These two sets of control devices furnish a coupling between the tie-feeder load variation and the combustion rate in the boiler. The first set, the load-frequency controller, translates tie-feeder load variations into variations of steam pressure by actuating the turbine valves. The second set, the combustion control, translates the variation in steam pressure into variations in boiler combustion rate.

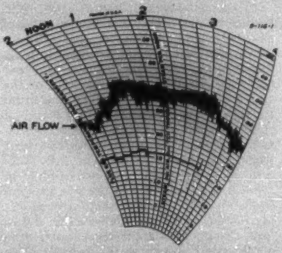

Figure 1. Section of Bailey boiler-meter chart typical of conditions as on September 4, 1940

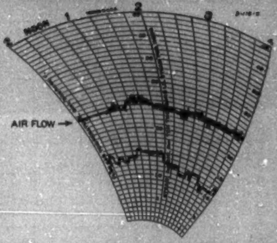

Figure 2. Section of Bailey boiler-meter chart typical of normal conditions

During the period from September 2 to September 10, 1940, increasing evidence of oscillation of the boiler control equipment was noted by the operators. Figure 1 shows a section of a Bailey meter chart of September 4 which is typical of the condition. It shows an oscillation of air flow of approximately 27 per cent and an oscillation in steam flow of approximately 10 per cent, the oscillation being periodic with a period of approximately three minutes. That a coupling existed via the frequency-load controller was established at various times by reducing the governor motor response drastically, which in all cases caused a complete cessation of the boiler oscillations. For comparison with normal conditions, figure 2 is given. The oscillations in boiler output did not appreciably affect the tie-line load. At the time of this trouble it seemed obvious that an increase in the fluid damping, obtainable by restricting the by-pass of the various dashpots in the individual regulators of the combustion control system, should solve the problem. When, however, adjustments were made in this direction, it was found that the oscillations increased in amplitude. Therefore the reverse procedure was tried. When the by-pass valves on these dashpots were opened, thus decreasing the fluid damping and with it the time constant of response, the oscillations ceased. The period during which this hunting of the combustion control equipment occurred coincided with the first cold weather and affected the viscosity of the oil in the various dashpots.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): The authors of the paper on "System Load Swings" are to be congratulated on the excellent series of tests which they conducted.

The authors found as outlined in conclusion 2 that changes in frequency did not appreciably change the load provided voltage was maintained constant. On one large interconnected system tests indicated a change of approximately one per cent change in load for a change in frequency of one-tenth cycle. These tests were made by increasing the output of certain plants by the amount necessary to increase the frequency one-tenth cycle, and by decreasing their output by an amount necessary to decrease the frequency by one-tenth cycle. Tests were carried out both during heavy and light load periods with the ratio of load change to total load remaining practically constant.

In connection with conclusion 3 it should be pointed out that the period of the magnitude and period of the inherent and average load swings on tie lines depend on the size and characteristics of the system.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The information given in the papers by Mr. Wild and by Messrs. Bauman, Manz, McCormack, and Seeley regarding the variation of load with sustained changes in voltage and frequency and the damping characteristics of tie lines, is of fundamental importance for the proper study of system performance.

Both of these papers show that the solution of their problems of frequency and tie-line control were obtained chiefly by refinements in the supplementary control, either automatic or manual, which act on the speed governors. Our studies have indicated that the speed governor to fit into this scheme should operate with stability and respond accurately to the frequency and load control mpulses. Close frequency regulation and load allocation for interconnected systems is properly the function of the supplementary control.

Mr. Wild's comment as to what he considers to be satisfactory requirements for governor sensitivity and regulation is appreciated, and we hope that his work will encourage operating engineers of other systems to determine what they believe are rational requirements for their systems.

H. A. Bauman, O. W. Manz, Jr., J. E. McCormack, H. B. Seeley: In answer to Mr. Wright's question, we wish to state that calculations have been made to determine the effect of voltage on system load by assuming certain percentages of types of load and combining their individual characteristics. Since a test to determine the relation between load and voltage can be made very readily with the normal control and meter equipment, we feel that it is not worth while to depend upon elaborate calculations based upon unknown variables.

Messrs. Wild, Brown, and Marquis have presented some interesting data on the relation of frequency and load on other systems. It should be emphasized that the tests on the Consolidated Edison system were made at a station that served a representative block of load and was isolated completely from the system. The frequency was varied by throttle adjustment and the voltage held reasonably constant while the generator outputs were totalized on one sensitive metering device. During the test there was no noticeable change in load when frequency was varied about three per cent.

With the station connected to the rest of the system other tests have been made in which the system frequency was raised by increasing the generator output at one station. These tests indicated that it was necessary to increase the generator output about 20 megawatts in order to raise the system frequency 0.1 cycle. The total load increase appeared on the ties and was about one per cent of the system load. The graphic meters at the other stations showed no apparent load decrease, but we believe that there was a proportionate decrease in load at the other stations because of the drooping characteristics of turbine governors. The sensitivity of the graphic meters is such that this 20-megawatt change in load proportionately distributed would not be readily perceptible against the background of short-time load swings. This latter test is not to be confused with the test reported in the paper where a representative block of load was completely isolated and totalized on one meter.

In addition to the data reported in the paper there were several by-products which proved valuable. A few operating problems developed in connection with consumer utilization equipment and several minor operating weaknesses were revealed on our system and later corrected. Clarification of these difficulties has simplified the task of the operators if the system should separate during trouble. The most valuable by-product developed during the tests was the interest of the station operators and their general appreciation of the problem. The willing application of the knowledge obtained and the use of the newly installed common frequency standard have resulted in a reduction of the load swings so that they are no longer a problem within the Consolidated Edison system. We feel that these by-products in themselves more than paid for the tests.

Methods of System Control in a Large Interconnection

Discussion and author's closure of paper 41-80 by Earle Wild, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 232–6.

E. E. Stevens (Commonwealth Edison Company, Chicago, Ill.): Mr. Wild's paper covers a large field in what has been and what is being done to cope with the interesting problems of frequency, time, and load control among the large interconnected power groups of this country. From the results obtained during the past several years through the conscientious efforts of those responsible for this type of control, I believe that in general a high degree of co-ordination has been attained.

However, as in practically all instances of engineering endeavor, we have not and probably never will arrive at a point where we are willing to let well enough alone.

The ultimate in co-ordination of this type of control, as I now see it, would be the employment of one reference frequency-time standard common to a whole interconnected power system. This standard would probably be in the form of a crystal controlled oscillator.

Another interesting problem is in the automatic control of the output of generating stations in maintaining them on a predetermined load schedule. This form of control should be centralized with respect to the generating stations of an operating company. The logical location would be in the load dispatcher's office.

Another step in the control problem is the automatic control of the loading of individual generators in order to operate them at good efficiencies. This control would naturally be under the supervision of the generating station personnel.

P. B. Juhnke (Commonwealth Edison Company, Chicago, Ill.): With reference to the paper by Mr. Earle Wild, dealing with methods of system control in a large interconnection, these remarks appear warranted.

It is interesting to note that in the particular interconnection in which the methods described in this paper first came to fruition, the basic principle of regulation was agreed upon at a meeting of representatives of the group about 15 years ago. This principle is the one outlined in the paper and specifies that the work of regulating frequency shall be carried on by one given station, while interconnected systems shall merely co-operate, the degree of co-operation depending upon the burden it is expected to place on the interconnected systems. This principle basically is still in vogue. It has been modified by frequency bias and time interlock, but essentially it is the same old principle that is working well, aided materially by the modifications which have been effected.

Next I would like to recall Mr. Sporn's suggestions of some years ago, to install frequency controllers in most of the principal stations of the interconnection and let them all operate in unison. That proposition was different in principle from what we have been conforming to and from what we are doing today, and could be made to work only if we had regulating impulses to guide all the participating stations and, what is equally important, proportionately equal increment or decrement responses. Mr. Sporn's proposal, on account of the difficulties in the way of all conditions for its successful operation, was never put into effect, but the proposal was helpful nevertheless. It was helpful because it resulted in the installation of a number of frequency regulators in various parts of the interconnected system and the co-ordination of these various regulators in the manner described in Mr. Wild's paper. Today this system is equipped to function with a degree of perfection unthought of some years ago, provided all participating parties discharge their full responsibility in the matter of providing necessary reserve capacity required to meet all emergency or ordinary demands of a widely spread out system.

Mr. Wild also devotes considerable space to the relation of controllers to governors. With proper and reliable frequency controllers, if employed adequately, the sensitiveness and regulation of governors become less and less important, except during those brief periods when large variations in the ratio between load and capacity take place. The more important requirement in the regulating turbine responding to such controllers is a more adequate valve characteristic, so that the response of the machine may more closely conform to the dictates of the frequency regulator without excessive reversals of contributions.

In figure 1 the diagram might have been a little clearer if it contained another set of three lines from bottom left to top right, depicting the condition obtaining for a tie line feeding in. The three lines in figure 1 now show this condition only for the tie line feeding out.

H. A. Dryar (Philadelphia Electric Company, Philadelphia, Pa.): Mr. Wild's description of the control of frequency and of tie-line loading of the largest interconnected group of systems in this country is of particular interest as a presentation of the method of regulation found to be satisfactory to the great number of power systems comprising this large group.

The great inertia of these tremendous reservoirs of power to change in speed and the continued presence of the frequency control problem may be said to indicate a failure through the years to recognize the fundamental problem in speed control as that of satisfactory turbine governor operation. Efforts of the past two years have served to crystallize opinion in this respect as former assumptions have not withstood a more thorough investigation.

The great inertia of these tremendous reservoirs of power to change in speed may be reflected in a number of ways:

1. A single regulating station would be subjected to excessive variations in output.

2. Changes in generations to bring tie-line loading to schedule.

(*a*). May affect the speed but slightly if turbine governors are sensitive to such changes in speed.

(*b*). May affect the speed appreciably if turbine governors have too broad a dead band.

(*c*). Subsequent correction of the speed in (*b*) may again find the governors active, upsetting tie-line loading again and resulting in seesawing of frequency and loading of stations.

3. Changes in system load that find turbine governors inactive will cause appreciable changes in speed. Again manual correction may initiate seesawing of load and speed as governors again become active.

4. If turbine governors are sufficiently sensitive, the self-regulating characteristic of interconnected systems should increase with their size as diversity in the load swings are greater.

Consistency of Governor Response

When a speed change occurs and manual changes in the output of a generating station are directed with the frequency meter as a guide, lack of consistency in governor performance creates considerable confusion in the mind of the load dispatcher as to what measures should be taken.

Where governor dead band is small, appreciable changes in the speed will indicate an appreciable change of load. The relatively small change in generation made to bring tie-line loading to schedule would have a negligible effect on the speed. Thus the load dispatcher may proceed with assurance that the measures he directs will be the proper remedy.

Scheduled Tie-Line Loading

The economical operation of a group of systems does not differ from that of an individual system. Any change in the interconnection load is allocated to the marginal system in the same manner that a change in the load of an uninterconnected system is allocated to its marginal station. Thus the loading of the interconnection tie lines may vary in amount and direction throughout the day in the same manner as the loading of the system ties may change.

Frequency Effect on the Load

The effect of change in speed on the system load is not synonymous with the effect of a load change on the system speed as seems to be implied. The general rule to which reference is made may be "a one per cent change in the load will cause a change in speed of one-tenth cycle." This ratio will differ from that of other systems if there is a difference in the response of turbine governors. In the interconnected group of systems of which the Philadelphia Electric Company is one, this ratio, when governors are active, is as follows: A change in load of two per cent will cause a change in speed of one-tenth cycle.

Correction for Droop

As the system load increases, the speed will decrease. If the turbine governors are sensitive to a change in speed, the decrease may be negligible. If the turbine governors do not have a narrow dead band, the change in speed will be appreciable.

Where governors have a narrow dead band, correction for droop as a result of load changes occurring on the plateau of the load curve may be considered unnecessary as speed changes will occur within a narrow frequency band, one counteracting the other, due to the regulating characteristic of responsive governors. During the normal heavy load change periods of short duration, regulation of the load and frequency does not present the same problem as variations are in one direction and changes in loading may be directed without confusion.

Regulating Capacity

In the operation of an interconnected group of systems with approximately 100 generators or more, operating in parallel, the availability of an appreciable number of these units with sensitive governors would find load changes absorbed with negligible effect on the loading of each generating station and relatively little sustained change in the loading of tie lines.

Conclusion

Greater sensitivity of the governors, more uniform response throughout its range, and a reduction of the average speed regulation should provide more consistent control for all changes in speed regardless of degree and promote intelligent regulation of the load.

V. M. Marquis (American Gas and Electric Service Corporation, New York, N. Y.): We are in general agreement with the ideas expressed by Mr. Wild in connection with the speed control of large interconnected systems. The central system of the American Gas and Electric Company operates in parallel continuously with a company which is in turn interconnected with the Chicago system. Frequency is held automatically at our Philo and Windsor stations. Combination automatic frequency and tie-line control is in operation at our Twin Branch, Cabin Creek, and Claytor stations.

As to Mr. Wild's fourth conclusion I am not sure that we know enough about our governors to say that the sensitivity and per cent regulation may vary inversely with the size of the system and nature of the loads. I, of course, note that Mr. Wild does not make a definite commitment on this.

S. B. Crary: For discussion, see page 737.

Earle Wild: The author is pleased with the many favorable comments which he received in the discussion of the paper. In general, there was no disagreement with the principles which were stated in the use and application of the auxiliary speed control devices.

The question was raised by several as to correctness of the figure of a one-tenth-cycle frequency departure causing a one per cent change in system load. In the paper by Messrs. Bauman, Manz, McCormack, and Seeley, the figure indicated no change in load, while in Mr. Dryar's discussion there was an indication that this figure might be even larger than one per cent. It is generally felt that this characteristic is the function of the amount of large industrial load in any system, and it is very likely that the different types of load served in different areas produce the variations in the frequency-load characteristic. The figure quoted was the result of tests which were made at three different times of day, when the frequency was both lowered and raised to produce the load changes.

Mr. Dryar's discussion regarding the relation of governor action to frequency changes is appreciated. In general, there can be no disagreement with the fundamental principles which he states regarding need for sensitive governors. The speed governor is responsible for holding the instantaneous frequency. Now that means are available for testing governors, they should be used and steps taken to correct any excessive insensitivity that might be found. Mr. Dryar, however, probably does not appreciate that the auxiliary speed controllers are essentially load controllers. Probably 95 per cent of the time the frequency is within such close limits that the controllers are responding to real load changes occurring locally and not correcting frequency deviations. The speed governors, if left to themselves, would be allocating this load generally on all turbines of the interconnection. In Mr. Dryar's system, although it is large in capacity, it is compact with large transmission links, and all stations are on the call of one load dispatcher. This is vastly different from the large interconnection covering 16 states, 2 time zones, no plateau load period except for a few hours on Sunday mornings, and a variety of power flow agreements between the many groups. It is under these conditions that the auxiliary speed device has proved so practical on this interconnection, and, as pointed out in Mr. Juhnke's discussion, in the aggregate has given very satisfactory frequency and integrated time. Mr. Dryar's statement that the operation of a group of systems does not differ from that of an individual system may be theoretically true, but in practice each large group in the larger interconnection must handle its own load control problems locally.

In addition to the question of sensitive governors, the other point which has been raised concerns a decrease in the percentage regulation of the governors. This is quite debatable at the present time, especially on systems where the agreements require strict adherence to tie-line load schedules. The author personally feels that in the future it may be practical, after more thought has been given to better maintenance of the existing governors, to consider means for decreasing the per cent regulation.

System Stability

Discussion and author's closure of paper 41-49 by F. W. Gay, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section), pages 168-73.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The paper by Mr. Gay raises some interesting questions as to the phenomena associated with the pulling into step of units of a system which have lost synchronism with each other. The associated problem, prevention of loss of synchronism has been given a great deal of attention, resulting in rational system design practices from the instability prevention point of view. Among these has been a more general use of quick relaying and switching, particularly at locations near important generating stations and along the heavily loaded transmission lines. Although intelligent preventive means may greatly reduce the number of cases of instability, it may still be advisable to have a cure for those cases when the relaying and switching do not function properly.

One of the difficulties, pointed out by Mr. Gay is the tripping of overspeed devices following loss of synchronism. When a unit is out of step, it is subjected to a pulsating electrical torque at slip frequency. This torque produces a pulsation in the speed of the unit resulting in an increase in the instantaneous overspeed above that which would exist if this pulsating torque did not exist. The magnitude of the maximum instantaneous speed that may result due to switching off a fault at the most disadvantageous point (180 electrical degrees with respect to the system) may be expressed as,

$$\Delta S=\sqrt{\frac{T_m}{\pi f H}+(\Delta S_0)^2}$$

where

T_m = equivalent maximum of sine wave of pulsating component of electrical torque in times normal

$H=\dfrac{0.231\times WR^2\ (\text{rpm})^2}{\text{kw}\times 10^6}$ inertia constant

ΔS_0 = average per unit overspeed, corresponding to that of no pulsating component

ΔS = maximum instantaneous per unit overspeed

Figure 1 shows the relation between the maximum instantaneous overspeed and the average overspeed as a function of the pulsating component of electrical torque, T_m, and inertia constant, H. On the basis that the speed governor will prevent an overspeed of ten per cent on loss of full load, the average overspeed during a system disturbance will be less than ten per cent because of electrical losses during the fault. However, upon clearing of the fault the unit may be running out of synchronism and subjected to a pulsating electrical torque of appreciable magnitude. Fortunately, however, with the clearing of the fault, the average electrical torque due to the braking and induction generator torques will be appreciable on any unit running above average system speed, so that the average speed of the unit will be rapidly decreased. However, if the fault is cleared when the unit is between 180° and 360° out of phase with the system and during this angular interval the prime mover mechanical torque reaches about zero due to the closing of the steam valves by the governor, the instantaneous overspeed will tend to be a maximum, other conditions remaining the same. If for example, a severe three-phase fault occurs just off the generator bus when the generator is carrying full load such that the average losses during the period the fault is on are comparatively small, the unit may have a maximum average overspeed of six to 8 per cent. Then, if the fault is cleared when the unit is 180 degrees out of phase with the system, the instantaneous overspeed may exceed ten per cent, if the magnitude of the resulting pulsating component of electrical torque is sufficiently large and the inertia of the unit sufficiently small. See figure 1.

It will be noted from figure 1, that if the inertia constant is comparatively small, $H=3$ corresponding to a noncondensing unit and the pulsating torque sufficiently large, $T_m=5$ a maximum instantaneous speed of ten per cent may be obtained with a very small average overspeed.

The conditions which are most apt to lead to tripping of the overspeed device from this cause, with a governor which prevents tripping or complete loss of load are:

1. A severe three-phase fault just off the generator low or high tension bus.
2. Prolonged switching time of the order of 30 to 60 cycles.
3. High kilowatt load on the station, for example carrying a kilowatt load corresponding to full kilovolt-ampere rating.
4. Small turbine-generator inertia constant. For example, 3,600 rpm noncondensing units have a lower inertia constant than 1,800 rpm condensing units.
5. Low overspeed device setting, for example, set below ten per cent.

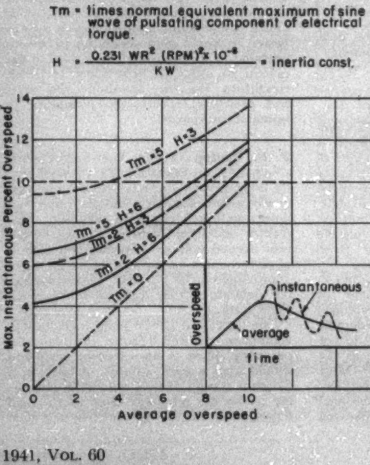

Figure 1 (left). Effect of negative half loop of synchronizing torque during out-of-step condition increasing the instantaneous overspeed above the average overspeed

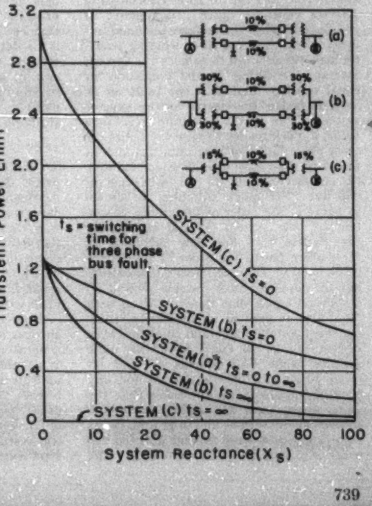

Figure 2. Transient power limits following three-phase faults on system having three-winding transformers compared with more conventional systems

All of these conditions need not exist at once, but they all tend to increase the possibility for tripping. Of considerable interest, is that the quicker the switching time even if it is not sufficiently quick to prevent loss of synchronism, the less chance there will be for high overspeed as the electrical braking torques will become effective sooner. Also, this will reduce the time required for pulling back into synchronism. Accordingly, the quicker the removal of faults, the more quickly the system will regain synchronism and the less chance there will be for tripping of the overspeed devices, even if the switch time is not sufficiently fast to prevent loss of synchronism.

The use of field adjusters to increase the field strength upon low voltage is an effectvie way to increase the steady-state pull-out torque of a generator and may prove particularly so if the unit is operating initially at light load upon the occurrence of a system disturbance, resulting in low frequency and subsequent increase in loading due to the governor opening the steam valves.

If the unit overspeeds when out of synchronism with the system, the more usual case, the field adjusters will increase the generator braking torque which varies as the square of the field current and also increase the synchronizing torque which varies directly with the field current, both effects increasing the possibility for resynchronizing with the system. One of the important considerations in the problem of pulling into step, is the desirability of accomplishing it quickly in order to prevent excessive heating and damage of the rotor structure.

The use of three winding transformers especially designed to reduce the fault severity on a bus section, as discussed in the paper, accomplishes this, but with a reduction in the power limit over the remaining healthy circuit after the faulted line or section has been switched off. Figure 2 of this discussion shows the transient power limits for a three-phase bus fault, as a function of system reactance for the three transmission systems shown in figure 1 (appendix) of the paper. The low-voltage terminal reactance branch of the three winding transformers was assumed to balance the system reactance, resulting in the condition of equal stability limit with the fault on or with the faulted line cleared for this type of system. This is the optimum reactance value, if it is intended to raise the limits for three-phase faults of long duration and at the same time have equally good stability for an insevere fault or just switching off one line. For quick switching as shown in figure 2, the order of preference is system (*c*) over system (*b*) and system (*b*) over system (*a*). For slow switching of three-phase faults, the order of preference is (*a*), (*b*), (*c*). However, with quick switching, the power limits of systems (*b*) and (*c*) are always better than those obtained with (*a*). Also, it may be impossible to transmit rated power for any fault condition with system (*a*), as all faults have the same severity, while with systems (*b*) and (*c*) rated power can be transmitted for any type of fault, with the provision that the more severe ones are quickly switched. Insevere faults such as line-to-ground faults occurring with systems (*b*) and (*c*) need not necessarily require quick switching. The advantages of this method (system *a*) can be compared by analysis against its disadvantages for any given system. However, it appears that the advantages are necessarily limited, as has been previously pointed out, to closely coupled systems having relatively short transmission line distances and where reliance cannot be placed entirely upon the relaying and switching to function properly.

Sherwin H. Wright (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The bulk of the engineering studies and literature on system stability has been devoted to means of maintaining stability and determining stability limits, and while the author has devoted attention to preventive measures, he has also given proper attention and consideration to curative methods to be used in case stability is lost. This is a logical step and that it has entered into system engineering is evidenced by the many applications of out-of-step relays to machines and lines where tripping action is taken after instability is detected.

The efficacy of quick response excitation used as a part of an automatic voltage regulator has been well proved in operation, and since the field adjuster mentioned by the author is a form of quick response, it should give the same benefits as on other systems.

Instead of using three undervoltage relays, one for each phase, the author can simplify the low-voltage relay scheme in cases where only three-phase machines are involved, by utilizing only positive-sequence voltage and a single relay with it. This is because the synchronizing power or pull-out torque of three-phase machines is determined largely by the positive-sequence voltage.

In the closing part of the paper the author suggests the further development and field trial of the several remedies or methods considered. It is believed that most of these controlled methods or remedies have already been developed and applied in one form or another to such a point that the only further development required is to determine just how far each control method need be carried in the particular system involved. This can best be done by the method indicated in the appendix—namely, by making a thorough system study on an a-c network calculator.

J. W. Jones (Philadelphia Electric Company, Philadelphia, Pa.): The paper is particularly timely and interesting in view of the expansion of power systems now under way and the increasing use of pulverized fuel boilers which are so susceptible to shutdown in case of a drop in supply voltage. Many ideas are suggested for improving the reliability of power systems and these ideas will warrant careful consideration.

A reference is made to field adjusters to automatically strengthen the field of generators in case of subnormal voltage. While these are undoubtedly a considerable improvement over no regulation, I do not believe they will be as satisfactory as the usual type of voltage regulator. Most of the generators on the Philadelphia Electric system are equipped with conventional type voltage regulators, in some cases having high-speed features, and no particular trouble has been experienced in their operation or in allocating reactive load as desired by the system load dispatcher. Field current is kept within safe values by means of limit switches on the field rheostats and fixed resistances in the field circuits.

The paper suggests a method of back-up relaying by means of separate low-voltage relays for each individual phase. It might be preferable to have a single low-voltage relay arranged to operate on the average three-phase voltage or the positive sequence voltage which might be obtained by means of a polyphase rectifier or a network. It also seems possible that the complication of a storage battery could be avoided by the use of available types of low-voltage relays.

The three-winding transformers mentioned in the paper which have negative reactance in one winding are a considerable departure from normal design and it would be interesting to know if this involves any construction changes that have an adverse effect on reliability or efficiency.

As pointed out in the appendix of the paper the use of the special three-winding transformers having negative reactance, improves stability while the fault is on the system, but after one part of the system is opened to clear the fault, the stability condition is less satisfactory than with the more usual transformer arrangement. Since most faults are cleared from the system in a few cycles and parts of the system may have to be kept out of service for an extended period it is questionable if the special three-winding transformers are worth while.

In considering voltage at the generator terminals under fault conditions for the two systems shown in figures 2 and 3, it is apparent that while the generator connected to transformer *T*-2 on one side of the system in figure 3, using standard transformers, may have relatively low voltage under fault conditions, there is a correspondingly greater voltage for the generator connected to transformer *T*-1 on the other side of the system, resulting in less possibility of losing both of the generators in case of a single fault. Under some circumstances it may be better, to permit some generators to become unstable or to drop load on a part of the system in order to have more favorable conditions for the remaining machines, and therefore, reduce the possibility of losing all equipment.

F. S. Benson (Pacific Gas and Electric Company, San Francisco, Cal.): We heartily concur with the recommendation that power plant auxiliary motors have sufficient pull-out torque to maintain satisfactory operation down to at least 60 per cent normal voltage. Oscillograph records of disturbances on our system show that at approximately 60 per cent normal voltage our generators often begin to swing against the system.

The suggested power plant loud-speaker equipment controlled from the load dispatcher's office is an excellent idea and should give a good account of itself in a compact system, that is, where the generating plants are relatively close to the load dispatcher's office. However, in a system where generating plants are hundreds of miles away and there are many such plants to be controlled, the loud-speaking equipment does not seem to be the practical solution.

It is difficult to determine how the generator field adjuster mentioned in the paper differs from the high-speed field excitation equipment now furnished with generators; additional information on this device would be appreciated.

The proposal that three-winding transformers having a high equivalent primary negative reactance be used is most interesting; however, the voltage rise to 200 per cent on the unfaulted line seems to preclude this scheme from being generally used as the connected equipment and lines should be constructed to withstand the insulation stresses due to double voltage. It seems, at this time, that high-speed relay and circuit breaker operation is still the better method to obtain the desired system stability.

F. W. Gay: Referring to figure 2 of Mr. Crary's paper, it is important to note that the upper two curves in this paper represent switching operations only. A fault which exists on a system for zero time is no fault at all. Since this paper considers only faults not promptly cleared, and since oscillograph records show that nearly all high-voltage single phase-to-ground faults develop into phase-to-phase ground faults in from 8 to 15 cycles and further develop into three-phase faults in a few more cycles, we must generally consider all sustained faults as three-phase faults, with the exception of pure phase-to-phase faults out on the span caused by "galloping" conductors. With a cross wind of gale proportions, a phase-to-phase fault may remain a phase-to-phase fault until a line burns down.

For sustained faults the upper two curves of figure 2 in Mr. Crary's paper must be thrown out and only the lower three compared. Fortunately, immediately following the clearing of a sustained fault, the system voltage (at least adjacent the fault) instantly rises to a high value and with properly designed field regulators or field adjusters on near-by generators falls slowly to normal value. The power limit varies as the square of the voltage, and in normal operation on a high-capacity system, the transient power limit following a sustained fault should not be much below the steady-state condition shown in figure 5*a*.

Field Power-Factor Testing of Transformer Insulation and Operating Experience

Discussion and author's closure of paper 41-31 by E. W. Whitmer, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 605–11.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): The author of this paper has presented a fine contribution on the usefulness of the power-factor test as a method for determining the condition of apparatus insulation in service. The power-factor test is a tool which, when properly applied, can give effective results. Paradoxical as it may seem, while the power-factor test serves a useful purpose in the field, its usefulness at the factory appears as yet to be rather limited. I have reference in particular to transformer apparatus. The reason for this becomes apparent from a consideration of the purpose each of the various tests primarily fulfills.

As the author states, in 90 per cent of the cases high power factor of insulation in the field is associated with the presence of moisture diffused in the solid insulation. A capacity higher than normal naturally is also recorded. In the other ten per cent, high power factor is attributed to the oil due to one cause or another. The remedy on the one hand is to dry out the insulation, and on the other to recondition or replace the oil. Both conditions are the result of service.

At the factory, 60-cycle and impulse dielectric tests have a distinct value for these are the tests that verify and check insulation design, workmanship, materials, etc., and that do establish the insulation levels built into the apparatus. A simple illustration is the case of a 115-kv insulation design that was tested to destruction. The power factor before and after the impulse tests, even though the insulation actually was destroyed, was the same, 0.60 per cent in both measurements.

It will be of interest to compare the limits of power-factor values as recorded on some 150 new power and oil-insulated instrument transformers. For the higher voltage classes (46 kv and above), power-factor values within the limits of 1.5 to 0.5 per cent are typical. Higher values in the range of 1.5 to 3.0 per cent are encountered in some of the lower voltage classes. In extreme cases, a value of four per cent may be found. All of these values are for a temperature of 20 degrees centigrade to 25 degrees centigrade.

The correction factors for the power factor versus temperature referred to room temperature are summed up in the following tabulation. The values in column 2 are representative. These approach the correction curve E. W. Whitmer presents in figure 5. Other values encountered are given in columns 4 and 5 and at the bottom of the tabulation. It is clear from this that no single set of correction values is generally applicable, other than as an approximation.

Power Factor of Transformers Versus Temperature (Multiplier)

Temp (Deg C) (1)	Multiplier for 20 Deg C (3,000 Kva, 14.1/2.5 Kv HV to LV and I) (2)	Multiplier for 20 Deg C, (Whitmer, Figure 5) (3)	Multiplier for 20 Deg C (450 Kva, 2.4/0.24 Kv)		Multiplier for 20 Deg C, (Ghen, EEI Journal) (6)
			HV to LV and I (4)	LV to I (5)	
20	1.00	1.00	1.00	1.00	1.00
25	0.76		0.875	0.86	
30	0.59	0.71	0.78	0.77	0.66
35	0.47				
40	0.39	0.48	0.65	0.62	0.42
45	0.32				
50	0.27	0.33	0.58	0.54	0.28
55	0.23				
60	0.194	0.23	0.53	0.48	
65	0.163				
70	0.137	0.16			
75	0.114				
80		0.11			

Other Examples of Multiplier From Experimental Data

Temp (Deg C)	Mult.	Temp. (Deg C)	Mult.	Temp. (Deg C)	Mult.	Temp. (Deg C)	Mult.	Temp. (Deg C)	Mult.	Temp. (Deg C)	Mult.
17	1.0	19	1.0	20	1.0	19	1.0	19	1.0	22	1.0
50	0.5	62	0.41	55	0.55	52	0.62	61	0.36	62	0.41
17	1.0	19	1.0	20	1.0	19	1.0	19	1.0	22	1.0
50	0.35	62	0.33	55	0.51	52	0.61	61	0.49	62	0.51

From the foregoing, the importance in selecting a suitable reference temperature should be noted. In our development tests at the factory, the capacitance was found to be relatively unaffected by the temperature, which fact is a measure of the high degree of drying of the insulation.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): This paper shows that considerable progress has been made since Mr. Gross published his paper in 1938, in using the power-factor method for the purpose of detecting moisture in transformer windings and bushings under service conditions. I note that the author used the words "insulation deterioration" in several places in the paper. In the usual sense, "deterioration" means that the insulation has been weakened either electrically or mechanically, and cannot be brought back to its original condition. A study of the records in the paper, however, shows that the power-factor tests indicate only the presence of moisture in transformer insulations. I am wondering if a more suitable word or words could not be used to describe the moist insulation.

The author states that faulty bushings can now be detected without disconnecting them from the transformer. In the cases shown where this was done, the power factor of the bushing was quite high, considerably above the minimum value that would be considered safe. I would like to ask Mr. Whitmer if he feels that a bushing, whose power factor is slightly above the safe value, can always be detected without disconnecting it? Whether or not this can be done, the paper shows that operating engineers now have available a promising means of preventing some transformer and bushing failures.

Eric A. Walker (University of Connecticut, Storrs, Conn.): The purpose of field tests on the insulation of any piece of high voltage equipment is to predict the safe operating life of the insulation. In these tests the quantity measured is the power factor and, although there are few, if any, curves relating the breakdown strength of insulation to the power factor, or curves showing a correlation between expected life and the power factor, some such relationship must exist or the method would not have achieved success.

Granting that some relationship does exist which makes a measurement of power factor a useful one, there are two questions which present themselves: First, if a dangerous condition exists in the insulation of a bushing or a transformer, is it usually a localized condition existing only in a limited area or does the condition tend to become general throughout the insulation? Second, is any such fault a linear one which is as prominent at low voltages as it is at high voltages? When these two questions are answered the scope of the tests can be defined.

Let us review the first of these questions in more detail. Suppose a square foot of insulation is being tested and one out of the 144 square inches is defective and all others are in good condition. Then a power-factor test will not reveal the defect. Taking a more specific case, suppose the power factor of the defective square inch is 0.9 and all other areas were perfect or had zero power factor. Then, if one assumes the capacitance per square inch is uniform, the over-all power factor would be about 0.015. This figure is not usually a reason to classify the insulation as defective. However, the test records for bushings and transformers show that few faults have escaped being predicted by a well-interpreted power-factor test. Therefore, the conclusion which must be drawn is that most insulation faults in bushings and power transformers are not of the spot variety but are a result of more general deterioration in the insulation. As the usual cause of deterioration is the entrance of moisture and as the moisture will rapidly permeate cellulose insulation, such results are reasonable.

The second question has to do with the linearity of the fault. It is well known that corona and other forms of gaseous discharges do not occur until a certain critical voltage is reached. It is also conceded that any such discharge in solid insulation is harmful. It is not without reason, then, that some have questioned the adequacy of 10 kv for testing bushings and transformers in the higher voltage classes. Yet again, the record shows that the majority of faults have been successfully diagnosed and a second conclusion must be drawn that the majority of insulation failures in bushings or transformers are not caused by gaseous discharges which are only detectable at operating voltage or, if the faults are of gaseous nature, they do permanent damage to the insulation before failure and this permanent damage can be detected at voltages under the corona voltage.

The next forward step in power-factor testing is the testing of cables and generators. Again, the same two questions must be asked. If faults in cables and generators are caused by over-all, rather than spot deterioration, and, if the deterioration can be found at low voltage, the test will become an important one. Obviously, these questions cannot be answered before a considerable amount of data has been compiled.

H. L. Cole (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): Mr. Whitmer has given us some interesting and valuable data on power-factor testing of oil-insulated transformer windings in the field. The results show that this method of testing, when carried on systematically, will indicate general insulation weakness in time to remove a transformer before failure.

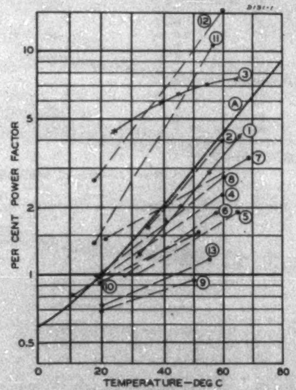

Figure 1. Factory power-factor tests on new transformers

A. Whitmer curve "A"

1. 3,000 kva (22 kv)
2. 65,000 kva (287 kv)
3. 450 kva (2.4 kv)
4. 24,000 kva (161 kv)
5. 10,000 kva (138 kv)
6. 10,000 kva (161 kv)
7. 3,333 kva (115 kv)
8. 667 kva (34.5 kv)
9. 750 kva (40 kv)
10. 333 kva (25 kv)
11. 1,000 kva (13.8 kv) Inerteen transformer
12. 1,000 kva (13.8 kv) Inerteen transformer
13. 500 kva (34.5 kv)

While many power-factor tests have been made at Sharon on new transformers, the power-factor method of insulation testing has been used mainly on solid insulation and oil, separately, rather than on a combination of the two. The power factor of new transformers is usually low (from three-fourths per cent to four per cent at 25 degrees centigrade). Differences in low power factors are difficult to explain. It may be that with further investigation these points will be explained.

It has been shown by test that high power factor which is due to acid oil or the presence of dipoles does not affect the impulse or 60-cycle strength of oil and pressboard structure adversely. Where free moisture is present (as is often the case in the older types of transformers) the high power factor and low strength will go together, but a considerable increase in power factor takes place before the dielectric strength drops—a fortunate thing.

On the other hand, a low power factor may not be an absolute indication of high impulse or 60-cycle strength. Damage to the solid insulation, either electrical or mechanical, can produce a condition which will not affect the power factor because the oil will fill up the damaged insulation. Low power factor is therefore principally an indication that there is low conductivity (due to absence of moisture and acid) and freedom from contamination.

The above points are mentioned here only to indicate that there are limitations in significance of the low-voltage power-factor test which should be recognized, particularly in regard to tests on new transformers.

In connection with figure 5 of Mr. Whitmer's paper, the accompanying curve shows some temperature power-factor data taken at Sharon on transformer windings. The measurements were made on the high-voltage windings. Curve 3 is for a 2,400-volt winding, and the major insulation is of a material having somewhat higher power factor than the other units. Curves 11 and 12 are for Inerteen transformers, which are higher, in general, than oil-insulated units.

It has been found that drying out windings with very low power factor may increase the power factor under certain conditions. This will occur when a transformer is removed from the oil and oven dried at approximately 100 degrees centigrade, and vacuum impregnated again. The heating of the oil-soaked insulation will produce some oxidation of the oil and will increase the power factor. One unit on which such a test was made showed an original measurement of less than two per cent, finally increasing to more than four per cent after drying.

C. F. Hill and **L. J. Berberich** (Westinghouse Research Laboratories, East Pittsburgh, Pa.): Data on insulation in apparatus in service are not only valuable to the operating companies as a maintenance economy and insurance of continuity of service, but also afford information to the manufacturer for the improvement of design and materials of his insulation. The presentation of papers giving such data should, therefore, be of great value to the electrical industry and we hope nonoperating engineers can be encouraged to publish their results.

The papers by Whitmer and others show

definitely that field tests are highly satisfactory on apparatus for which the insulation is subject to certain types of deterioration; namely, to the infiltration or formation of ionizable impurities. Moisture, products of oil oxidation, and even oxidation of organic insulations themselves are readily detectable by power-factor and resistance measurements and such impurities are very definitely a principal cause of insulation failure. This conclusion was more or less anticipated and the design engineer has attempted to protect his insulation from such influences. The data from papers giving the results of field testing should be of help to the design engineer toward further improvement.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): The field testing of insulation implies three requirements: First, a test method and instrument, that is capable of determining faulty insulation, with acceptable limits of precision under field conditions; second, an effective method of evaluating the seriousness of the faults; and, third, a means of locating the faulty insulation and correcting the condition.

Referring specifically to bushings, transformers, and similar associated equipment, the first requirement has been met with the available power-factor test set which the authors have used on their systems during the past ten years or so. Constant development and improvement in this test equipment and prompt servicing of it by the manufacturer, has kept it available for service at all times.

The second requirement, that the test results should permit a determination of the seriousness of the fault, has been fulfilled by a continuous collection, analysis, and study of field data and the establishment of power-factor rating limits for equipment of different classes, voltage, rating, manufactures, and types of design. This build-up of a sound background for determining the seriousness of insulation faults has resulted from the co-operative efforts of the companies who have been, and are now, carrying on field or service testing. This work has been greatly aided by the manufacturer of the power-factor test set we have been using, as well as by the equipment manufacturers whose apparatus was being tested in the field.

A constant watch is kept on the grading of the faults into good, deteriorated, and remove classifications, and revisions made as field experience justifies. This second phase of the work is important, if the greatest value is to be obtained from the test work.

The third requirement, that means should be available for specifically locating the fault when the over-all bad insulation condition is indicated, cannot be too strongly emphasized. For example, a 25-kv faulty bushing can be promptly replaced without detailed analysis to determine whether the defect is in porous porcelain, split porcelain, voids in the compound, or the like. But the situation is different in a 10,000-kva transformer, for example, where the fault must be specifically located and corrected.

The specific typical cases, in Mr. Whitmer's paper, where detailed analysis has been made of the field data to definitely locate the fault clearly indicates what can be, and has been, done in making the field data give up the secrets of faulty conditions and locations in composite insulation.

It may seem astonishing that relatively small differences of power factors, currents, and watts loss indicated on field tests are capable of telling so much about the quality of the insulation which is considered, and has proved hazardous under operating conditions. Such, however, is a fact, as proved by extensive tests.

Messrs. Baltzly and Schlottere have indicated that the scope of their field test work covers many other items besides bushings (as shown in the paper). Our field test work, likewise, follows very much the same pattern. Their statement that "All equipment rejected by test has, upon investigation, disclosed faulty insulation which warranted its removal from service," also agrees with our experience.

The idea conceived some ten years or more ago that it ought to be possible *and practical* to measure in the field the power factor of insulation and thus determine hazardous insulation conditions has now become an accepted practice in the industry. This has been accomplished, like many other research problems, only through determination that the job could be done and the broad-minded viewpoint of those who cooperated, particularly in its early stages, in carrying on the development. Now that a solution has been found, it is hoped that all concerned will bend their efforts to further perfect the tools and technique for the over-all benefit of the industry.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): This paper makes out a good case for power-factor testing of transformer and bushing insulation, but it seems to me that the really important facts about the apparatus have been stated in just three or four lines of the paper and these have nothing to do with power-factor testing. In effect, the paper states that moisture is the principal cause of the insulation deterioration, and that if gaskets and other joints and seals are kept tight most of the troubles will be eliminated. Thus, the most important conclusion of all that should be included in the paper is:

Every effort should be directed toward eliminating all openings into parts of apparatus where moisture might have any effect on the insulation. This would mean the elimination of all gasketed joints as well as open vents, and replacement of bolted-on covers, bushings, and other parts by some solid metallic method of jointing such as soldering or welding.

This should be done on all new apparatus and so far as possible on old apparatus, although I realize that in most cases for old apparatus we will have to be content with the best possible type of gasketed joint with the best available gasket materials.

If the above suggestions are carried out and existing apparatus is put in good condition, I feel confident that there will not be enough failures to justify much power-factor testing and the cost of operation can be reduced correspondingly. Objection might be raised that completely sealed apparatus would be difficult to repair. This can be met by building the apparatus carefully enough that repairs will be reduced to a minimum and by designing the sealing arrangement so that when it is necessary to open a unit the expense of doing so will be easily justified. It has been suggested that other methods of sealing might provide easier access and resealing than the existing methods.

It seems to me that the apparatus manufacturers should be quite receptive to sealed-up equipment as a means of reducing complaint calls and costs. So far as we know, no manufacturer has completely sealed apparatus that eliminates all gaskets, although some designs have a materially reduced number of gaskets. I should like to urge that they be reduced to zero.

E. W. Whitmer: Mr. Montsinger has mentioned the possibility of an occasional bushing with a slight fault being overlooked in an analysis of over-all test readings. This of course is possible but as pointed out in the paper, our operating experience has shown that on a practical basis the over-all tests are capable of indicating bushings which are likely to fail before another periodic test is made on the equipment. The collar tests which have been made on bushings during recent years are a great deal of help along this line.

The question of defining the deterioration of insulation in transformers has been brought up by Mr. Montsinger. In the paper the broad interpretation of deterioration has been used in which any decrease in the quality of insulation which makes it less suitable for service operation is considered to be "insulation deterioration." While possibly 90 per cent of such deterioration as indicated by power-factor test is caused by moisture, the remaining 10 per cent, of course, should not be disregarded. High power-factor oil and deposits of carbon or other objectionable materials on the insulation of transformer windings are some of the types of faults which have been located in this group of ten per cent or so of the faulty transformers. Investigations to determine the cause of such conditions have shown a number of transformers to be distinct service failure hazards. Since such faults as these or conditions of excessive moisture may be failure hazards the insulation of the transformer as a whole is considered to be "deteriorated."

Mr. Oldacre brings up the idea which has been prevalent in the industry for some time of welding all transformer tank joints and thus eliminating gaskets. It is pointed out in the preceding paragraph that some serious types of faults are not caused by moisture, and welding the tanks would not necessarily eliminate such troubles. To assume that all troubles in transformer insulation can be eliminated for the normal life of the equipment by simply sealing the tanks without other design improvements seems to be a case of wishful thinking rather than a hard and fast idea which is backed up by operating experience. The elimination of as many gasketed joints as possible from a practical standpoint seems a step in the right direction, but whether or not this should be carried to the complete elimination of all bolted and gasketed joints in all types and sizes of oil-filled transformers, is a subject which is open to a great deal of discussion and investigation. The advantages gained in eliminating gaskets should be weighed against the added inconvenience, expense, and skill of workmanship required in maintaining, breaking, and remarking welded joints as a matter of maintenance after the equipment is put into service. Field experience with some sealed up equipment is certainly necessary before such a practice is put into extensive use. Troubles on the inside of transformers, such as insulation faults, and bushing troubles will be with us no doubt for a great many years regardless of efforts made to retard their development, and a program of periodic checking by a comprehensive test like the power factor seems to be the only way now available in which we can be reasonably certain that the insulation is in good condition either in old or newer transformer.

The question of using one temperature correction curve for tests of all types of transformer windings has been brought up by Messrs. Bellaschi and Cole. It seems quite remarkable that all of the temperature power-factor data on both new and old transformer winding insulation yield correction factors which are so nearly alike. Whether or not the differences encountered are too great for practical use in making corrections from one average curve is the main question and further study may indicate that more than one curve is necessary. The test data presented by Mr. Bellaschi and also that given by Mr. Cole are the type of information needed. It might be expected that continued testing of transformer insulation at the factory will eventually prove useful not only in obtaining temperature corrections but in forming a bench mark from which to evaluate any future tests on the apparatus after it is in service.

The requirements for a field power-factor insulation testing program have been very appropriately outlined by Mr. Gross. Some of the ground work which has been done over the past ten years or so to bring the field testing art up to its present refinement is, of course, one of the things which has been necessary, and future efforts should certainly be made by everyone concerned to improve not only the test procedure and instruments but the equipment which is being tested.

Dr. Walker points out some of the fundamental considerations in locating concentrated faults in a large area of insulation. The location of some faults of this nature is, no doubt, difficult. While some progress has been made in transformer testing, a great deal remains to be done particularly in other types of equipment where the capacitance or area of the insulation may be much larger and the background of testing experience much smaller than for transformers.

Messrs. Hill and Berberich point out some of the fundamental things which influence the power factor of solid and oil insulation. It is gratifying to know that field testing of insulation is being studied by design engineers in an attempt to make further improvements in equipment. While power-factor testing of insulation in service has proved very important from a maintenance standpoint, there is, no doubt, possibility of a great deal of further improvement. The combined efforts of field, factory, and laboratory testing should do much to promote progress along these lines, and it is hoped that much valuable information will be forthcoming from all sources.

Bushing and Associated Insulation Testing by the Power-Factor Method

Discussion of paper 41-72 by C. C. Baltzly and E. L. Schlottere, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 308–12.

E. D. Eby (General Electric Company, Pittsfield, Mass.): The authors have made a helpful contribution to the literature and published data on this subject. The exchange of experience in this field is the strongest factor toward the establishment of a sound practice. The writer offers the following comments upon that part of the paper relating to bushings.

With regard to the adoption of a set of power-factor values, such as those in table *IA*, two things need to be kept in mind if the basis of rating is to be sound. In the first place, some insulating materials undergo an aging process with time which results in an increase in power factor, not dangerous in itself, but trending toward the rated limits. In some types of bushings this aging, which is not due to moisture, may require a graduated scale of limits according to age, or a higher initial limit.

In the second place, classification according to type may need to be refined further than is indicated in table *IA*. Normal power-factor values vary with the kinds and amounts of materials used. As a result, some types have inherently higher values than others. Some common types exceed the "satisfactory" limits in the table when tested new at the factory. The adoption of rating limits must recognize this fact by selecting suitable limits for each type, in order to avoid a false basis of rating and therefore excessive rejections in field tests.

The authors' present practice of basing replacement on the "satisfactory" limits rather than the "follow-up" limits seems a concession to expediency and ease of rebuilding. Unless the foregoing factors are given due weight, this practice may lead to some needless rejections. The "follow-up" testing to determine the trend, whether it be dangerous or normal, has its merits. This feature of the program might bear further study.

The facts that 69 per cent of bushing failures over the past nine years were due to moisture, and that 90 per cent of field rejections for high power factor were also due to moisture, when taken in connection with changed design practice, should be very encouraging for the future. This is reflected in figure 5 which shows the marked decrease in failures since 1935; and in table III which shows the reduced number of rejections in 1940 compared to previous years.

The greatly improved gasket practice on modern bushings naturally diminishes the failures and rejections due to moisture, and therefore reduces the percentage for which this cause is responsible. Reconditioning works to the same end, providing reliable gasket materials and assembly practices have been utilized. Gradually, old bushings with poor gaskets can thus be reclassified as rebuilt bushings with good gaskets. This would result in increasing the proportion of bushings on the system from which trouble due to moisture need not be expected, as was true of some of the older bushings. Eventually, when the older bushings have disappeared or been rebuilt, the moisture problem due to gaskets, as well as other sources of weakness from moisture, should diminish to a negligible minimum. Certainly, modern bushings, both in the matter of gaskets and in other moisture-prevention features, can be expected to give a very superior performance record, in comparison with some of the obsolete types.

In view of conclusion 9, favoring the centralized shop for repair work, the importance of designing bushings for easy and rapid disassembly and reassembly received further emphasis. Obviously, if the operating company is to conduct repairs on an economical and reliable basis, the designer must first provide a structure which lends itself readily to such procedure. In the best designs this is being kept prominently in mind, in order to facilitate such field work as may become desirable as a regular or emergency measure. Designs which require very special or expensive equipment to accomplish their repair, or which take excessive time or labor, are not to be looked upon with as much favor as those which facilitate such operations. This applies even in those designs which commonly give the least trouble.

The authors make no reference to the relative results of power-factor tests made on bushings at different times of year. It has been found by some observers that more failures, particularly those from moisture, occur in spring and fall than in summer and winter, especially in cold climates. It is not inconsistent to expect power-factor values to reflect a similar seasonal variation. On such a basis, it would appear more effective to make the tests during the periods of greatest danger, when the moisture content was greatest and the power-factor values highest. This could be expected to discover some units which might be in dangerous condition at one season, though returning to a passing condition at another. Since the purpose of field testing includes removal of units which constitute a potential hazard to the system, it would appear logical, in so far as such a practice is economically feasible, to select the most dangerous periods for the testing.

C. T. Pearce (Westinghouse Electric and Manufacturing Company, Philadelphia, Pa.): This paper shows the value of field power-factor testing as a guide for doing preventive maintenance of bushings and transformers. Operating experience of this nature has led the manufacturer to provide bushings with long-lived gasket materials that are protected from exposure to the outside air by suitable stops and with provision for taking care of the differential expansion between copper and porcelain. As a further protection against moisture, better waterproof bushing plastics have also been developed. The condensers for both indoor and outdoor types of bushings since 1937 have also been given special moisture resistant treatments prior to varnishing, and better varnishes have been used. With modern condenser bushings we anticipate the test period interval can be extended.

A background of experience for power-factor testing of oil-filled transformers in service is rapidly being built up and this paper is a valuable contribution. The gradual accumulation of moisture in transformers shows up during the tests made from year to year. These tests are particularly valuable for the older transformers that breathe in outside air containing moisture. For many years the larger transformers have been protected by using nitrogen over the oil and excluding outside air. This method has been so successful in keeping out moisture and preventing oil deterioration that our company is now sealing some of the smaller power transformer tanks completely. It is believed that the methods of sealing are sufficient that the moisture problem will become negligible.

Under the heading "Field Testing," an arbitrary value of five per cent power-factor maximum at 40 degrees centigrade is mentioned. This corresponds to only 2.1 per cent at the 20-degree-centigrade base used by the Doble organization and appears to be rather low. We believe that the authors intended this figure to be one of the classification limits instead of a maximum value. This belief is based on the grouping under the heading "Transformers."

During manufacture, transformers are dried out with hot air, followed by the application of a vacuum before the windings are initially immersed in oil. We have found that the leveling off of Megger readings is as reliable an indication of the end of the drying-out period as that given by power-factor readings. When the transformer is dry, it is immersed in oil and power-factor readings have been found to fall within about a seven-tenths to four per cent range at 20 degrees centigrade, depending on the type of construction and voltage class. At the present time, we feel that factory power-factor measurements are of little value but that field tests taken from year to year will indicate by unusual changes the presence of undesirable moisture conditions.

In order to avoid confusion, it is recommended that some reference temperature for power-factor testing of transformers be standardized by the industry. There is a wide variation with temperature and a fixed point of reference is necessary.

The Audio Noise of Transformers

Discussion on paper 41-10 by W. C. Sealey, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 109–12.

J. P. Barton: See discussion, page 749.

Suppression of Magnetic Vibration and Noise of Two-Pole Turbine Generators

Discussion and authors' closure of paper 41-39 by A. L. Penniman, Jr. and H. D. Taylor, presented at the AIEE winter convention, Philadelphia, Pa., and published in AIEE TRANSACTIONS, 1941 (June section) pages 283–8.

E. F. Dissmeyer (The Commonwealth and Southern Corporation, Jackson, Mich.): The authors provide a very interesting discussion of the problem of suppressing the magnetic vibration and noise produced in two-pole turbo generators. Although experience with large 3,600-rpm generators has been comparatively short, operating experience indicates that it is essential that the 120-cycle vibration be limited to minimum possible values. It is not possible to anticipate resonant conditions which may be experienced in the plant itself, relays, disconnects, and other associated equipment. Trouble is usually encountered before a resonant condition is detected.

In most cases after a condition of excessive vibration has been noted, it is possible to apply remedial measures to eliminate the trouble. Cases have been encountered where complete isolation of a device from foundations, etc., will not eliminate vibrations. Evidently the vibration can be air borne and may be of a sound nature. The wave length of this sound is so long that ordinary acoustic materials cannot be used to shield equipment. It is, therefore, essential that all lagging and other flat portions of the machine be so constructed that they do not provide a source for these sound waves. It is recognized that excessive noise in a generating plant is conducive to fatigue of operators which may lead to operating mistakes and accidents.

It appears that the use of a resilient core mounting should reduce the vibration and noise emanating from the generator a considerable amount.

If the rotor in a generator is not located in the magnetic center of the stator, the unbalance magnetic pull may become appreciable. Would it be possible to experience trouble with a resilient core mounting in case the rotor is not properly centered due to poor alignment of bearings, etc.?

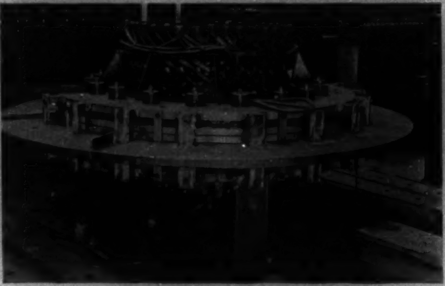

Figure 1. Experimental stator test model

B. A. Rose and M. D. Ross (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The last report of the AIEE power generation committee emphasized the fact that the problem of double-frequency vibration and noise of two-pole turbine generators had not been satisfactorily solved in the machines then in operation and stated that this was the major problem left to be solved in these large high-speed machines. The company with which the writers are associated started up the first of their large 3,600-rpm units in August 1937, and the experience gained at that time indicated that something would have to be done on these large two-pole units to make them comparable in noise and vibration to the 1,800-rpm units which had formerly been used for these generator ratings. The double-frequency stator vibration reacted unfavorably on foundation parts, relays, instruments, and many other parts of the power plant equipment, and special steps had to be taken in certain cases after these first generators were put in operaton to shift parts out of resonance with the 120-cycle frequency or isolate the smaller parts with flexible mountings. While the earlier machines have proved by more than three years' service to have been satisfactory as regards reliability, the development of the flexibly supported stator core has removed one of the major objections to the two-pole, 60-cycle generator.

The authors have presented a very interesting and complete discussion of the phenomenon of double-frequency generator stator vibration. It is interesting to note that they reach the same general conclusions regarding the solution of the problem that C. M. Laffoon and B. A. Rose presented at the AIEE convention at Springfield, Mass., in May 1939. It is also very interesting to note the similarity between the spring suspension members used by the authors and those embodied in the model on which we made our preliminary investigation. The attached figure 1 shows a photograph of the experimental model which was built and tested in 1938 to obtain verification of the calculated performance of the core when vibrating under the influence of the magnetic forces in the air gap. The heavy outer ring represents the generator frame. The core is composed of 12 inches of actual stator punchings with a special winding designed to produce flux variations identical to those in an actual machine.

Figure 5. 81,250-kva 3,600-rpm generator having flexibly mounted stator core, built for Consolidated Edison Company of New York

The flexible bars which support the core in the frame are axially situated members which fasten to the outer frame ring at their centers and to the core itself at their ends. The performance of this model was entirely satisfactory and gave the same results which the authors present.

A study of the model in figure 1 will disclose the fact that the flexible tie bars were themselves quite similar to those used in the authors' design except that they were much more rigid tangentially. They were purposely proportioned in this manner to demonstrate whether or not extreme flexibility in the tangential direction was necessary for satisfactory performance of the mounting. As can be noted from the photograph the bars were fastened to the core by spacers which maintained a certain fixed radial position of the flexible bars with respect to the neutral axis of the core cross section. It was found by this test that if the flexible supports were attached to the core at a point beyond the neutral axis equal to one-third the radius to the neutral axis they would have to absorb no tangential motions. This fact was conclusively demonstrated by tests on this model as well as on the several machines which have subsequently been built.

It is very interesting to observe how well the authors' data on the tangential motion of the core agree with the above results. Our figure 2 combines figure 7 and data from figure 8 of the authors' paper to illustrate this point. The outlines of the core are superimposed on the elliptical curve, representing the neutral surface of figure 8. The value of the tangential motion for a ratio of outer diameter to inner diameter of 1.6 are taken from figure 8 of the paper and plotted to scale at their respective positions on the diagram. Lines connecting these points are normal to any circumferential line in the core and if extended a short distance outside the core's periphery intersect at a point of zero tangetial motion. This point as may be seen from a brief study of figure 2, lies at a radius of $1^{1}/_{3}R$ where R is the radius of the neutral surface.

It can be seen from a study of the above information and that contained in the authors' paper that two solutions to the problem are available. One involves the use of supports which are flexible in both the tangential and radial directions and which are clamped to the outer periphery of the stator core. The other involves the use of members having flexibility in only the radial direction which are fastened to points of zero tangential motion just outside the core surface. The Westinghouse company knew of the two solutions and decided to use the second for the following reasons:

1. Its use eliminated the problem connected with the ability of the assembly to withstand the short-circuit torques of the generator. These torques can be as high as 10 to 15 times the full load rating of the machine and anything which can be done to strengthen the supports is well worth while. The supports can be built as rigidly as desired in the tangential direction, thereby allowing an easy and more satisfactory solution to this problem.

2. By the use of an inner frame in which the stator core is securely clamped, the flexible support members could be fastened to the core in the correct radial location to obtain zero tangential motion and afford a construction which would allow easy

Table I. Vibration and Noise Data on Three 3,600-RPM Generators
Vibration Is Given as Double Amplitude

Machine Description	No Field Excitation					Normal Full Load Excitation				
	Average Core Amplitude	Average Frame Foot Amplitude	Average Frame Cover Amplitude	Average Over-all Sound Level (Db)	Average 120-Volt Sound Level (Db)	Average Core (Amp)	Average Frame Foot (Amp)	Average Frame Cover (Amp)	Average Over-all Sound Level (Db)	Average 120-Volt Sound Level (Db)
81,250-Kva hyd. cooled 3,600-rpm generator resilient core mounting	0.0002	0.00015	0.00016	100	91	0.0015	0.0002	0.00029	101	95

Sound data should not be noted for absolute values since the ambient level was rather high and variable from day to day. The decibel values should be used for comparison only.

An interesting although not pertinent observation is that on both of the above-mentioned machines with flexible mounted core, the motion at the base of the spring mounted studs in both the horizontal and vertical direction was so small as to give meaningless values of vibration with a velocity type vibrometer (something less than 0.05 mil).

access to all flexible members for replacement should any fail in service.

3. The stator core is known to be vibrating and from experience with other large machines, it is known that the best construction for these machines is the one which provides a core and support assembly which are tightly clamped together. Unless the supports are so fastened to the core that no slight movement or rocking of one with respect to the other is allowed, trouble may be encountered with wear of the contact points. This is eliminated by the use of the inner frame which is built in two halves and clamped tightly to the core after the core has been built and pressed together.

Figure 3 shows a diagrammatic arrangement of the construction used by the Westinghouse company. Three sets of tangential tie bars support the inner frame and core. These bars are quite rigid in a direction tangential to the core but flexible in the radial direction. The two sets of vertical bars are quite heavy and they act as the major support members taking care of the weight of the core as well as the torques of the generator. The horizontal tie bars act only to center the core in the frame and maintain the air gaps.

As a result of tests on the model of the stator core, the Westinghouse company decided to build and test a 10,000-kw, 3,600-rpm turbine generator incorporating the design as shown in figure 3 and this machine was completed and tested in the early part of 1939. This machine is shown in table I. Extensive tests of noise and vibration with the flexible mounting in operation and with it blocked out by wedges between inner and outer stator frames proved conclusively that the desired results could be obtained in such a design Over 40 short circuits were made on the machine during an investigation of short-circuit torques and the flexible suspension system was therefore given the most severe testing it could possibly get in service. It withstood these tests without failure of any kind.

As a result of the tests on the 10,000-kw generator it was decided to standardize on the flexible mounted stator construction on all the large two-pole, 60-cycle generators and 23 of these units are on order or have been shipped. To date four units have been built and tested with very satisfactory results. Figure 4 gives comparative readings of noise and vibration on three large 3,600-rpm generators. The first two units have the new type core mounting while the third is of the earlier design. It will be noted from a study of these results that the outer frame vibration of the generator with flexible supports increased but a slight amount when excitation was applied whereas that of the conventional machine increased to a large extent. The increase in noise level around the machines is also of interest because both the over-all level as well as the 120-cycle component increased much more with the conventional generator. In line with the experience of Messrs. Penniman and Taylor, it was found that it was impossible to tell by observation when the generator field was applied in the case of the units with the flexible mounting.

The 81,250-kva unit shown on test in figure 5 and the results of which are shown in figure 4 is of interest as representing the largest 3,600-rpm generator yet built. The test results indicate that the noise and vibration of even the largest units can be expected to be excellent.

A. L. Penniman, Jr., and **H. D. Taylor:** Answering Mr. Dissmeyer's question about the possibility of trouble being experienced with a resilient core mounting due to unbalanced magnetic pull in case of the generator field not being properly centered, this might be a real hazard if the core mounting is made as elastic as the conventional type of isolating mounting, which is often rather "floppy." The resilient mounting developed by the General Electric Company and described in the paper is very far from being floppy; for radial displacement of the core, this mounting is actually stiffer than the solid steel rotor. Furthermore, these resilient mountings are applied only to large two-pole machines, in which the air gap is relatively long (about $1^1/_2$ to 2 inches radial length), and in which the gradient of unbalanced pull per unit of displacement off center is inherently low. This is because of the fact that all of the flux entering the rotor through one pole must go out through the other, so that the unbalanced pull is due only to differences in distribution of flux, rather than in amount of flux as in machines with more than two poles. We are confident that there is no danger whatever of trouble from unbalanced magnetic pull with the type of resilient core mounting we have described.

Messrs. Rose and Ross' comments imply that our conclusions regarding the solution of the problem are in general the same as those presented in the Laffoon and Rose paper of 1939. In a very broad sense, this is true, in that we agree that the inherent magnetic vibration of two-pole generator cores cannot be eliminated, and that the most effective way to suppress its effects is to isolate it by means of a resilient core mounting. However, we wish to reiterate that the alternative solution of the deep core-type generator, together with judicious layout of station structures based upon experience, is even more "practical," enjoying the advantage of employing design features proved by long and successful service. Half a dozen or more machines of this type have gone into service within the past year, all of which operate satisfactorily, without objectionable vibration and noise.

Messrs. Rose and Ross made quite a point of the similarity between the spring suspension members used on the Baltimore generator and those employed in the experimental model described by Laffoon and Rose. As a matter of historical interest, the Baltimore spring bars had been designed and some had been made and tested long before the presentation of that paper.

The indirect suggestion that extreme flexibility in the tangential direction is required, if the point of support is not moved out radially to a position well outside the core, is likely to give an erroneous impression. It has been pointed out that the type of resilient mounting used on the Baltimore machine is not of the conventional "floppy" type, but is very stiff for radial displacements of the core. For tangential displacements, it is actually stiffer. The tangential stiffness could be even greater yet, without much change in the effectiveness of the isolation, but this is limited by the requirement that the torsional frequency of the core on its mounting be low relative to 60 cycles, as pointed out in the paper. It may be noted that the spring suspension system used in the Baltimore generator is rigid lengthwise of the machine.

With regard to the relative merits of

the two varieties of spring mounting, the first with both radial and tangential flexibility and the second with extreme radial flexibility but rigid tangentially, there are quite a number of considerations involved, and there is undoubtedly room for differences of opinion. Either type can undoubtedly be built to give creditable results. The reasons for the choice of the first type by the General Electric Company may be summarized as follows:

1. It gave promise of being more effective; that is, of affording a higher ratio of improvement.

2. It avoided the necessity for a double frame, which is not only a complication, but actually seems to work against the effectiveness of the isolation, because the outer frame is necessarily more shallow than it otherwise might be, and this affects its stiffness and resonance properties unfavorably.

3. The manufacture and installation of such a design appeared to be more simple and practicable.

4. While there were other problems involved, particularly with regard to the mechanical effects of rotor unbalance and short-circuit torques, these were by no means insuperable, as was indicated in the paper.

With regard to the question of the ability of the generator to withstand transient short-circuit torques of the order of 10 to 15 times the full load rating of the machine, it should be noted that quantitatively, this is not nearly so drastic as it sounds. This is because, for a speed of 3,600 rpm, rated torque is quite low, and even 10 to 15 times rated torque amounts to only two or three times the gravity load that the spring bars are carrying continuously. The problem is one of resonance, to avoid a condition which would amplify the disturbance. This is accomplished by designing for a moderately low torsional natural frequency of the core as mounted in the frame. Also, the problem is greatly ameliorated by the fact that the disturbing short-circuit torques are transient, and die away so rapidly that there is not time to build up much torsional displacement.

The authors do not know about the trouble with wear of core contact points to which Messrs. Rose and Ross refer. It is clear, however, from the tests described in the paper and illustrated in figures 4 and 5 that, so long as the core itself is tightly compressed between its flanges, it matters little or not at all whether there is a frame around it or not, so far as its magnetic vibration is concerned. The difference in the support of the core between the Baltimore generator and machines with solidly mounted cores is that, whereas in the latter the long dovetail key bars are welded to the frame and keyed to the core, in the Baltimore machine they are keyed to the core and bolted to the spring bars, which in turn are bolted and welded to the frame. In the solid construction, the key bars are an integral part of the frame, and are subject to a microscopic amount of tangential "working" against the core at the dovetails, which has never been known to do any harm. In the spring-mounted construction, the key bars are an integral part of the core and flange structure, and by virtue of the slight flexibility of the spring bars, there is no occasion for any "working," except the intentional slight flexure of the spring bars themselves. In other words, so far as we can see, there should be no wear of contact points whatever with the Baltimore type of spring mounting.

A companion to the 81,250-kva, 3,600-rpm unit mentioned by Messrs. Rose and Ross has been shipped to the same customer. It has the same rating, and is of the deep-core construction. Its operation on test in the factory was excellent. Several other machines of about the same physical size and quite a number of smaller ones are being built with resilient core mountings similar to the one in service at Baltimore.

A Study of Sound Levels of Transformers

Discussion and author's closure of paper 41-53 by H. Fahnoe, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 277-83.

Clifford Mannal (General Electric Company, Pittsfield, Mass.): Mr. Fahnoe's paper is a contribution to the art and undoubtedly represents a summary of a number of years of investigational work. There are four points, however, on which I wish to comment:

1. It is stated that core-type transformers may possess a larger number of natural resonance frequencies than shell-type transformers. This arises from the inference that core-type transformers may vibrate in several planes while the shell-type transformer vibrates only in a single plane. My own studies on core-type transformers indicate that the motion is sensibly in one plane for all practical designs of clamping used on transformers of commercial design.

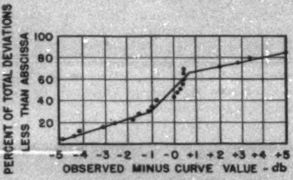

Figure 1. Deviations of observed values from curve values

2. A second point concerns the excitation of the higher resonance frequencies of the core by higher harmonics of the flux frequency. On the basis of a mathematical analysis which makes relatively few assumptions, the higher core vibration frequencies cannot be determined to closer than five per cent. At 600 cycles the uncertainty amounts to 30 cycles. Superimposed on this uncertainty is the shift of the observed from the computed frequencies due to the additional constraints on the core imposed by the oil, tank, and windings. The magnitude of this shift differs from one resonance frequency to the next and can only be estimated very roughly.

Beyond this, there is a basic difficulty which increased computational accuracy cannot remove. The flux in the core may be represented by a fundamental and integral multiples of the fundamental. The resonance frequencies of a rectangular frame cannot be so represented. The natural resonance frequencies of the core are not integral multiples of some fundamental resonance frequency. This is exhibited in curve 6 of the paper. Resonances are indicated at 136 and 292 cycles. The ratio is 2.13. Data given in figure 7 show intervals of 36, 56, 166, and 42 cycles between successive resonance frequencies. A small rectangular core investigated at Pittsfield has resonance frequencies at 696, 756, 1,360, 2,135, and 3,150 cycles.

Since the driving force has components equally spaced along the frequency axis and the core has resonance frequencies unequally spaced on the same axis, any choice of core proportions will locate some of the higher harmonic flux frequencies at or near the core resonance frequencies.

3. It is significant in this connection to examine the practical importance of the higher harmonics of transformer cores. Sound analyses made on a large number of transformers invariably indicate a relatively smooth decrease in the intensity of each succeeding component of the sound. If the higher harmonic resonances were significant from a practical standpoint, a pronounced increase in sound radiation at some particular harmonic frequency should have been observed in at least one of the transformers which have been studied. That this has not been observed seems reasonably conclusive evidence that higher harmonic resonance is not a significant contributor to the sound level of transformers. Resonance at the fundamental or second harmonic frequency would, of course, be a serious matter. Computations and tests have shown, however, that for cores of sizes now used, the fundamental resonance frequency is either well above 120 cycles or is capable of being located at a frequency sufficiently far removed from 120 cycles.

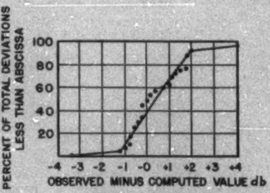

Figure 2. Deviations of observed values from computed values

4. Mr. Fahnoe points out that the sound level in the immediate vicinity of the core face in air may be computed from the dimensions of the core and the characteristics of the steel used. The figure of practical importance is the average sound level radiated by the assembled transformer. A possible method of attack might be to reduce the analysis into four portions:

1. A computation of the amount the core vibration amplitude in the completed transformer is reduced below the amplitude obtained in air.

2. The pressure produced by this reduced vibration amplitude on the tank wall.

3. The tank wall amplitude produced by the pressure as computed under 2.

4. The radiated sound produced by the tank wall vibration.

The subject of sound level in transformers has been under active investigation at the Pittsfield Works of the General Electric Company for the last decade. A large number of transformers have been measured and a quasi-empirical relation between the sound level and the factors of major importance in determining the sound level has been established. Figure 1 shows the deviations of individual transformer sound levels from the best average curve drawn on a decibel versus kilovolt-ampere plot. These transformers ranged in size from 1,000 to 11,000 kva. It can be seen that only some 30 per cent of the values fall within the limits of plus or minus one decibel. The second figure shows a typical distribution of the deviation between observed and computed values. It can be seen that almost twice as many points fall within the limits of plus or minus one decibel as for the previous figure.

Two points of importance are exhibited by these figures: first, that the relation between kilovolt-amperes and sound level cannot be expressed by a simple relation; and second, that the major factors underlying sound level in transformers are known and are subject to engineering control.

J. P. Barton (Carnegie-Illinois Steel Corporation, Pittsburgh, Pa.): I feel that Mr. Sealey and Mr. Fahnoe are to be congratulated in presenting these two pioneering papers (in this country) on the noise generated by large transformers, and some of the engineering aspects of controlling the level of this noise. Of particular interest is the fact that calculations made with the equations shown in Mr. Fahnoe's paper yield values that are quite compatible with those obtained by Mr. Sealey on the finished transformers.

In early 1940, a paper was published in England in the Metropolitan-Vickers Gazette, titled "The Limitation of Transformer Noise," by Mr. Churcher and Mr. King. This paper is of considerable length, covering many aspects of the cause and generation of transformer noise, as well as attempts by soundproofing and other means to prevent the noise from being transmitted at levels obnoxious to human beings in the vicinity of the transformers.

In this paper is given a curve showing the relation between flux density and change in length of silicon steel that may be of interest in consideration of the amplitude of the fundamental and harmonics of the sound generated by this magnetostriction effect in silicon steel. They show that the change in length for increasing values of flux density are not the same as when the flux density is decreased, thus giving a shallow "U" shaped loop for plus or minus values of flux density. This loop would indicate the power used because of the magnetostriction effect, in a manner similar to the power used as illustrated by a hysteresis loop.

The equations 2, 4, 8, and 9 of Mr. Fahnoe's paper, for a core length of 200 centimeters and Δl values in the vicinity of 1.5×10^{-6}, yield decibel values that check very closely with those shown in figure 3 in Mr. Sealey's paper. It should be observed that increasing or decreasing the value of Δl ten times gives a change of 20 decibels, which is a considerable change in sound level.

Of greater interest is a further calculation which appears to tie together quite definitely the equations of Mr. Fahnoe's paper with the observations on finished transformers by Mr. Sealey. From magnetostriction data on transformer grades of silicon steel such as commercially used in large power transformers, average values of the changes in length for various flux densities were substituted in the combined equations 2, 4, 8, and 9 of Mr. Fahnoe's paper using a core length of 200 centimeters and a frequency of 120 cycles. The difference in sound level between 8 and 14 kilogausses from these calculations, was ten decibels, which is the same value for the same range in flux density as Mr. Sealey shows in his figure 2, which is based upon actual tests. It might be added that this good agreement would tend to show that stray sources of sound or noise have been fairly well eliminated, leaving as the primary source of noise the magnetostriction effect in the core.

It is recognized that the type or shape of the core construction will modify the application of these equations in some cases. Also, that other factors will exert their effect in causing the noise of the finished transformer to be higher or lower than calculated. However, such agreements as stated above are indeed gratifying, and illustrate the progress being made in predicting the noise emitted by the finished transformer.

H. Fahnoe: Mr. Mannal's interesting discussion brings out certain facts which were not emphasized in the paper, but which are in line with our experience. In the majority of commercial core-type transformers the core vibrations are principally in a plane parallel with the laminations, but occasionally the designer is forced into abnormal designs in which the core may vibrate in another plane. An interesting case was a core-type transformer for which a very limited floor space was specified. This necessitated a rather tall core structure of relative small core area.

Calculations showed that the fundamental resonance frequency for vibrations in the plane perpendicular to the laminations was approximately 95 cycles and for the "box type" mode, parallel with the plane of the laminations, approximately 145 cycles. The actual measured resonance frequencies were 98 cycles and 150 cycles respectively. At 60-cycle excitation the sound level is approximately what would be expected from the magnetostriction characteristic of the steel, and approximately 15 decibels less than that at the resonance frequencies.

Mr. Mannal made a particular point in his discussion that mechanical resonance of the core at the higher frequencies did not appreciably add to the measured sound level caused by magnetostriction when resonance with the fundamental flux frequency was avoided. I agree, that with present-day transformer steel, it has also been our experience that it is only necessary to design the core of such dimensions that its fundamental resonance frequency is well above or below the fundamental flux frequency.

Protection of Power Transformers Against Lightning Surges

Discussion of paper 41-79 by the AIEE transformer subcommittee, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 568–77.

V. M. Montsinger (General Electric Company, Schenectady, N. Y.): For the benefit of those using this report, I believe that it will be worth while to work out a couple of cases showing how to use the data when providing protection for transformers.

The two cases selected for illustrative purposes are (1) a transformer having standard insulation, and (2) a transformer having one step below standard insulation. In both cases the transformers are for operation on a 138-kv system.

The figure shows on the left the transformer insulated for 115-kv insulation level for operation on a grounded-neutral system. The winding volt-time curve is based on 625-kv chopped wave at three microseconds and longer, 540-kv full wave. The turnup is based on figure 3 of the paper. The flat part of the bushing curve is based on a withstand test of 550 kv. The solid line shows the level to be protected against winding failure and bushing flashover.

The insulator volt-time curve is shown to indicate the magnitude of impulse voltages that can be imposed on the transformer if no protection is provided. Reflection will, of course, increase the voltage at the transformer.

The negative wave volt-time curve of a 20-inch rod gap is included. It is seen that even a 20-inch gap will not protect the transformer for steep front waves. Moreover by following the dashed (---) line drawn in from the 60-cycle flashover of the 20-inch gap over to the switching surge curve, lower right-hand corner, it will be seen that the gap would be expected to flash over and cause outages on 40 per cent of the switching surges. A 20-inch gap, therefore, is an entirely unreliable means of protection for this setup.

In selecting the proper lightning arrester, the line-to-ground voltage of the 138-kv grounded-neutral system is increased 40 per cent to take care of any possible increase in fundamental frequency voltage. The nearest standard station-type arrester rating above 110 kv $(138/\sqrt{3} \times 1.4)$ is 121 kv rms. The average gap breakdown for 121-kv arrester rating, according to table I, is 430 kv. Since the AIEE standard time of breakdown is based on a voltage rise of 100 kva per microsecond per unit and as there are (10) arrester units required, this fixes the first point on the gap breakdown curve at 430 kv for 0.43 microsecond time. The remainder of the curve is based on curve shown in figure 7.

The *IR* voltage values for 1,500, 3,000, 5,000, 10,000, and 20,000 amperes are taken from table I for 121-kv arrester rating. These voltages are shown at approximately five microseconds time for the reason that five microseconds is the approximate time

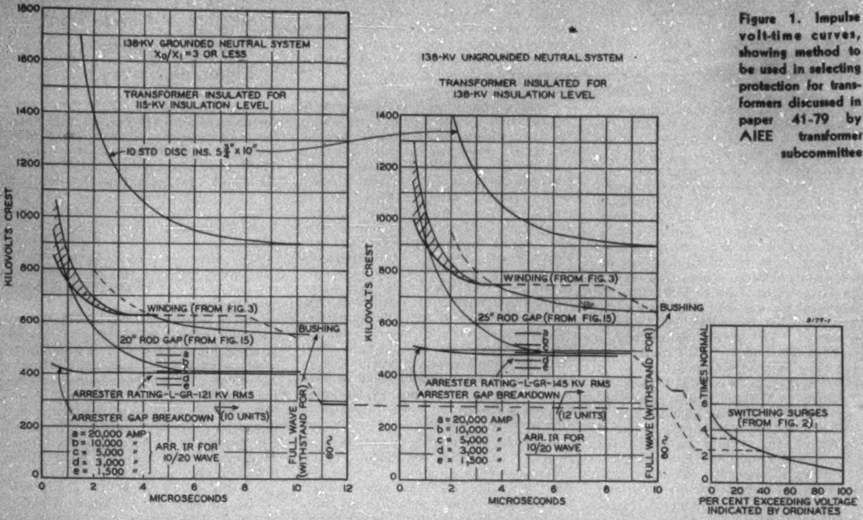

Figure 1. Impulse volt-time curves, showing method to be used in selecting protection for transformers discussed in paper 41-79 by AIEE transformer subcommittee

the voltage reaches crest value for the standard AIEE arrester 10/20 current wave.

The curves to the right of the figure are for a transformer insulated for 138-kv insulation level, for operation on a 138-kv ungrounded neutral system. These curves were worked out in the same manner as just described. In this case the arrester rating is based on line-to-line voltage of 138 kv, for the reason that if one line becomes grounded full line-to-line voltage is imposed on the arrester. The 40 per cent increase is not used here, since it is not likely that the fundamental frequency overvoltage will occur during the time one line is accidentally grounded. The nearest standard arrester rating is 145 kv.

A 25-inch rod gap is shown. Again it is seen that a 25-inch gap will not protect the winding for steep waves. It will be noted that the 25-inch gap would be expected to flash over on 20 per cent of the switching surges.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): This report of the AIEE transformer subcommittee marks another milestone of progress in the protection of power transformer against lightning surges. The comments I have on the report pertain to items that may require further study. I have specific reference at this time to the curve on switching surges in figure 2. It has long appeared to me that the experience from various important sources would justify segregating this general curve into two or more specific curves. The question is more than academic, for switching surges bear a relation to rod gaps and to their settings. As it is evidenced from figure 18 in the report, rod gaps come into the picture of protection and they are likely to remain in the picture to a greater or less extent in future developments.

To illustrate the point, we find the experience on the Chicago 12-kv system, recently reported by Messrs. Wollaston and Plumley [AIEE Transactions, volume 60, 1941 (June section), pages 260–5] sets an

Table I. Arrester Performance Data Taken From References 22, 23, and 24

Arrester Rating (Kv)	Average Gap Breakdown Crest Kv		Average Voltage (IR Drop) Across Arrester

242	860		720	768	806	872	940			

Note: Gap breakdown taken on rate of voltage rise of 100 kv per microsecond per 11.5-kv rating. All test currents 10/20 wave. The 60-cycle spark-over potential of all arresters shown in this tabulation will not be less than 150 per cent of arrester rating.

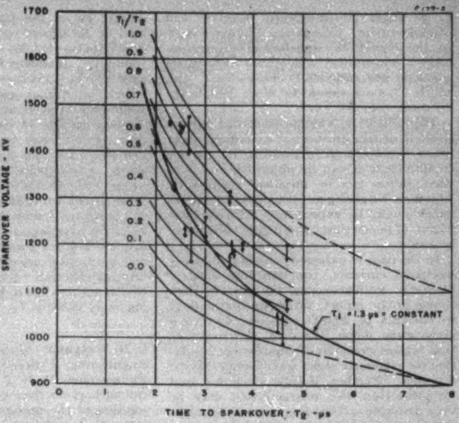
upper limit of 3.5 times the line-to-ground voltage for the highest switching voltages recorded over a period of many years. Rod and sphere gaps were used for the measurements in this investigation. This is a cable system with the neutral in effect solidly grounded. Other important sources of experience and data on this subject matter are references 16, 5, 6, etc., in the report, and in addition the various EEI reports.

In the light of these experiences and data, it would appear that data relating to switching voltages and to similar system overvoltages require some segregating if the curves are to be of more practical use. One curve could probably be drawn for the grounded neutral, in which case from the experience cited, this curve would intersect the zero ordinate at 3.5. One or more curves may be necessary to relate the conditions encountered from the operation of ungrounded neutral system, of systems operating with the neutral grounded through a relatively high impedance, etc., where higher system overvoltages than 3.5 line-to-ground voltages may be developed.

Figure 2. Time to sparkover—T_2 microseconds

Sparkover volt-time area of 50-inch rod gap. Boundaries are $T_1/T_2=0$ and $T_1/T_2=1$. Negative polarity. Standard conditions of humidity and air density

T_1 = effective wave front; T_2 = time to sparkover; points indicate measured values. Arrows point to correct location of test point based on T_1/T_2. T_1 = 1.3-microsecond curve from tests with 1.5x40 wave



W. J. Rudge (General Electric Company, Pittsfield, Mass.): This report is of particular importance and interest because it lists the various recognized factors which must be taken into account when selecting and designing the lightning protective equipment for power transformers.

The report is of greatest value in those items dealing with protection where specific performance values of protective devices available to the industry are given. I refer to the data on lightning arresters, protector tubes and gaps, as these data make possible the evaluation of protective margins.

The report points out that generator overspeed, system switching surges, arcing ground, and circuit harmonic voltages all should be known and evaluated. There have been numerous papers presented before the Institute which resulted from analytical studies, field tests, and transient analyzer studies which constitute ways for evaluating these overvoltages in terms of normal line-to-neutral voltage which is nearly always taken as the reference base. The normal line-to-neutral fundamental frequency voltage is also the base that is usually used for the selection of arrester ratings, and since there are systems having the same nominal circuit rating but which operate at voltages both above and below the nominal rating, it would seem in order to suggest that a survey be made of all systems under the sponsorship of EEI and associated operating companies, listing the actual operating voltages for the various systems, giving both average, minimum, and maximum values. The information so obtained would be to the advantage of both the user and manufacturer of apparatus as it is well recognized that successful standardization of ratings and designs depends upon selection of ratings which will be suitable to the majority of systems.

It is of particular interest to note the tentative volt-time curve shown in figure 15 of the report for plain rod gaps. In connection with this curve I wish to call attention to a paper by J. H. Hagenguth entitled "Volt-Time Areas of Impulse Sparkover" [AIEE TRANSACTIONS, volume 60, 1941 (July section), pages 803–10]. Mr. Hagenguth shows a wide spread in spark-over voltage values occurring on rod gaps, bushings, and similar apparatus, depending on the shape of the applied surge voltage. It is pointed out that these wide areas of sparkover, particularly at short times, show the futility of trying to use a rod gap or bushing as a protective device.

In figures 1 and 2 of the transformer committee report data are given on lightning strokes and tower currents, also switching surge voltages. Probably of greater significance are the currents which have actually been measured through station-type arresters which give both the magnitude and frequency of occurrence. Messrs. Gross and McMorris presented a paper before the Institute last January which gave the results of such a field investigation.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper shows the standard insulation tests for power transformers in table I. One of these tests is the impulse test requiring two chopped waves and one full wave at a stated minimum crest voltage. The requirement of impulse strength of the order indicated in the table has improved the design of transformers. However, it should be remembered that the mere fact that a transformer passed a test with impulses of the kind shown in table I will not be complete proof that the transformer winding is immune against surges of different wave shape. Furthermore, even if the transformer passes standard impulse tests, this is not a proof that no failure of any kind did occur. It is at present impossible to detect failures in the winding during impulse test if the percentage of winding involved is smaller than two to three per cent, such as turn-to-turn failure. Of course, from tests made on full-size models, the manufacturer knows the safety factor built into his transformers, but this can only be established by disassembling the winding and thorough investigation of the turn insulation. This procedure, of course, is out of the question for finished transformers receiving commercial tests. The best means available for detecting failure is by the use of a full wave with an amplitude of about 70 per cent or lower of the full-wave amplitude required by table I. If the comparison of the 70 per cent and 100 per cent wave shows any differences, failure of the winding is indicated. This 70 per cent wave should, therefore, be one of the requirements of the standards.

The methods of protection are clearly presented in the order of their effectiveness. One of the protective means mentioned is the rod gap. Tentative volt-time curves of rod gaps are shown in figure 15. As pointed out in the paper, the rod gap is the least satisfactory of the discharge devices. The rod gap has:

1. A marked polarity effect.
2. No sealing characteristics requiring frequent opening of circuit breaker due to switching surges.
3. Steep volt-time characteristic, requiring low spacing to obtain spark-over voltages below the transformer insulation—volt-time characteristic for all wave shapes.
4. A spark-over characteristic markedly dependent on atmospheric conditions.

In a paper which I am presenting at this convention, it is shown that the rod gap exhibits even more undesirable characteristics. The impulse sparkover of the rod gap cannot be represented by a simple volt-time curve, such as shown in figure 15 of the paper, but rather by a volt-time area. A volt-time area means that for a given time to sparkover the corresponding spark-over voltage is not a single value but varies within wide limits, for instance at 2 microseconds to sparkover of a 50-inch rod gap at negative polarity, the spark-over potential varies between 1,130 kv and 1,630 kv as shown by figure 1 (this discussion) or by 44 per cent based on the lower value. This variation of spark-over voltage is not due to erratic behavior of the rod gap but is due to variations in the wave shape of the applied impulse. This spark-over range compared with the curves shown in figure 15 of the paper corresponds to a variation of gap spacing between 43 inches and 65 inches. It is clear that such a device does not provide a very dependable discharge path especially when used in parallel with transformer insulation.

F. J. Vogel (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): In the report on transformer protection, there is one subject which is of importance which is not completely worked out, and which I believe should be more completely determined later.

This subject is, whether increased voltage strength of transformers at extremely short times is necessary, depending on service conditions, if it can be obtained, and if so what values can be obtained reasonably. This includes giving an idea as to gap lengths which might be expected to furnish some degree of protection, where gaps alone may be used.

In the case of extremely steep and heavy discharge currents, the lightning arrester discharge voltages may be greater than shown in the report, which limits the data to currents of 20,000 amperes, and to a given wave shape. In turn, this indicates that higher strengths of transformer insulation for extremely short wave fronts may be desirable. Further, if gaps alone are used for protection, this characteristic may be very desirable. That it can possibly be obtained is indicated in figure 3 of the report. In order to obtain an idea of what might be reasonably done, I would like to make an example of the 115-kv voltage class, having a 3-microsecond strength of 625 kv. If the upper curve of figure 3 were used, a strength of approximately 145 per cent of that at 3 microseconds would give over 900 kv, which would also be equivalent to testing with a 25-inch gap, from curve figure 15, at 1,000 kv per microsecond. If the lower curve figure 3 is used, the voltage value would be 800 kv and the gap length 20 inches. If no additional margin were required, a 20-inch or 25-inch gap might be expected to provide reasonable protection for steep waves, provided it were immediately at the terminals. Also, at 3 microseconds a 25-inch gap would flash at 560 kv, compared to the 625-kv transformer strength, and at about 490 kv for long waves against a transformer strength of 540 kv.

This discussion is not given for the purpose of advocating any definite procedure, but to show how such station gap lengths might be obtained. Probably many operators would feel that these gaps are too small for operation. A further caution should be given, and that is, that this increase in transformer insulation voltage strength at short times is not necessarily obtained, except with great care in design and construction, and if it is to be counted on, a test would be required. This has been under consideration in the transformer subcommittee.

Negative Damping of Electrical Machinery

Discussion and authors' closure of paper 41-12 by C. Concordia and G. K. Carter, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 116–19.

M. M. Liwschitz (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by C. Concordia and G. K. Carter represents an important contribution to the problem of negative damping. It solves the most complicated case in which primary resistance as well as series capacitance and steady-state power limit have influence and gives a new criterion on hunting due to the primary resistance. The authors have found that the hunting criterion $r \leq x_q \tan \delta$, of reference 1 of the paper, is too optimistic for small generator angles and too pessimistic for larger angles. This checks with calculations made by myself. I have found that the values of the negative damping as given by reference 1 are too low for small positive angles δ as well as for any negative angle δ. The new hunting criterion $r \leq x_d' \tan \delta$ as proposed by the authors has to be checked for at least one more value of T_0.

C. N. Weygandt (Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.): I wish to congratulate the authors on their complete and rigorous solution of the problem of negative damping. Also, and I speak from experience, I can well appreciate the labor that was involved in testing the roots of the determinant in equation 4.

The only thing that the paper lacks is some experimental checks of the new points of interest disclosed by the theory. Since we have at the Moore School a machine of the type studied by the authors I have made a few tests of the case when the machine is connected to an infinite bus through resistances. Figure 1 of this discussion shows the results of these tests. By comparison with figure 1 of the paper it can be seen that qualitatively the tests check the theory excellently. There is no question about the fact that the curve for higher excitation crosses that for lower excitation as predicted. Also the test curves bear the same relation to the old criterion $r = x_q \tan \delta$ as the theoretical curves of figure 1. It will be interesting to see whether the quantitative check is as good, as soon as time is available to draw theoretical curves for the actual machine tested.

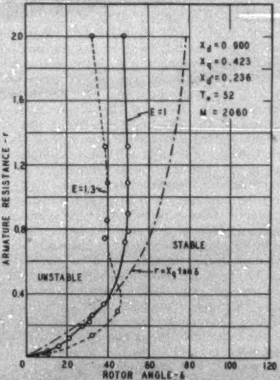


Figure 1. Experimental curves of stability limits, 31.3-kw machine without amortisseur connected to infinite bus

During the test it was observed that the hunting at low values of resistance was much more violent than for high values of resistance, and also that period was shorter. The violent hunting was of course accompanied by rapid swings of armature current, which in turn induced currents in the field circuit. This could easily be observed from the pulsating of the needle of the field ammeter. It seems logical since there must have been an a-c component in the field circuit that $x_d' \tan \delta$ would be a better criterion than $x_q \tan \delta$.

C. Concordia and G. K. Carter: We are very pleased to find that qualitative checks of part of our analysis have been made by both discussers. The test data presented by Mr. Weygandt are especially interesting and are a remarkable confirmation of the rather peculiar contour of the stable region which our calculations showed. Mr. Liwschitz has also found that damping torque calculations made on the basis of the formulas of reference 1 of the paper deviate from his more accurate results. However, as he has shown in his paper,[1] the more commonly used methods of equation 64 of reference 8 of the paper or equation 2 of reference 2 of this closure show no such discrepancies. We agree with Mr. Liwschitz that the hunting criterion should be checked at other values of T_0, and shall do so as soon as time permits.

Analysis of Short-Circuit Oscillograms

Discussion and author's closure of paper 41-2, by W. W. Kuyper, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section) pages 151–3.

C. F. Wagner (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Kuyper has raised a very interesting point in interpreting the oscillograms obtained on three-phase short circuits of unsymmetrical machines. In order to form an idea of magnitudes of errors that might result in basing the measured reactance upon the distance between the envelope of the alternating component of short-circuit current, I have made some calculations for short circuits from no load in which the decrements were neglected, that is, instead of projecting the alternating component of current to zero and thus determine the component before it has decreased, it was assumed that there was no decrement. In addition, the assumed envelope was taken as the actual envelope instead of the envelope Mr. Kuyper used as it is a more definite quantity, especially at small values of α. The results of the reactances so obtained expressed as a fraction of the correct value are as follows:

α	0	30	60	90
x_d'' for $\frac{x_q''}{x_d''} = 1.5$	1.0	0.98	0.96	0.95
x_d'' for $\frac{x_q''}{x_d''} = 3.0$	0.98	0.91	0.87	0.86

The departure from correct values is sufficiently great that consideration should be given to this factor. It would be interesting to see a comparison of the theoretical work with results of actual measurements upon machines.

W. W. Kuyper: Mr. Wagner has pointed to the phenomenon of saturation and has suggested that a comparison of results on actual machines with the theory would be of value.

The writer's experience with short-circuit oscillograms of solid-rotor, two-pole synchronous machines indicates that saturation has greater effect on the wave shape than is apparent in the differences between the symmetrical-component and two-reaction theories. Limited studies of oscillograms of short-circuit currents of salient pole machines have indicated that the two-reaction theory should be used in analysis but that saturation disturbs the magnitudes and wave shapes to such a degree that correlation of theory and practice becomes difficult.

Because it did not seem advisable to embark upon what would necessarily have been an indefinite discussion of the complexities introduced by saturation, the subject was avoided. The purpose in presenting the paper was to point out that—based on the two-reaction analysis of the ideal machine—some of the accepted methods of analysis for certain quantities do not appear to have justification.

The Water-Cooled Steel-Tank Rectifier Corrosion Problem

Discussion and author's closure of paper 41-25 by Emil J. Remscheid, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (April section) pages 173-8.

R. O. Nixon (Deceased, formerly of Philadelphia Transportation Company, Philadelphia, Pa.) and **C. T. Pearce** (Westinghouse Electric and Manufacturing Company, Philadelphia, Pa.): In connection with the problem of corrosion of water-cooled steel-tank rectifiers, it is believed that the results of some recently completed tests at the Erie substation of the Philadelphia Transportation Company will be of interest. This station comprises three Westinghouse 1,500-kw, 600-volt rectifier units. Each unit consists of two 750-kw, 6-anode tanks, mounted in a common framework, with one tank above the other.

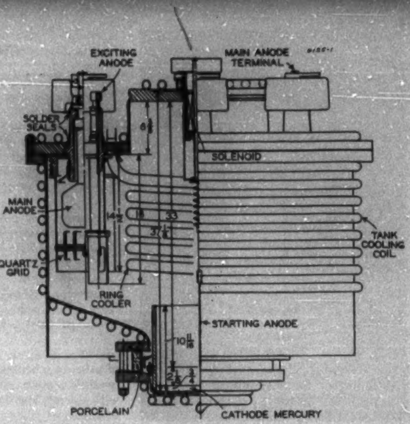

Figure 1. Cross-section view of a rectifier section

A cross-section view of one of the rectifier sections is shown in figure 1. Cooling is obtained by means of a continuous copper pipe welded to the rectifier tank. Each two-section rectifier is equipped with a heat exchanger and a water circulating pump so that the cooling water may be recirculated through a closed system. By-passes with valves are provided so that the heat exchanger can be by-passed and the raw water circulated directly.

In order to ascertain what corrosion and deposition effects would be obtained with raw city water used for cooling, one of the rectifiers, designated as 1, had the heat exchanger cut out by means of the valves and by-passes. The water circulating pump was left in the circuit to provide control and velocity. The performance of this unit was then compared with that of rectifier 2, which was operated with the heat exchanger.

During the tests, hourly readings of d-c kilowatt-hours, cubic feet of cooling water used, and the temperatures of the inlet and outlet water were taken. Water meters were installed in such a location as to measure the total water supplied to the rectifier, including that required by the mercury vapor vacuum pumps.

The results of this test over a year's duration starting October 1, 1939, are given in table I, which is self-explanatory. The variation in water inlet temperatures throughout the year is reflected in the ratio of d-c kilowatt-hours to the cubic feet of cooling water. The outlet temperature of the water from the rectifiers was held substantially constant by means of the temperature regulating valve. The over-all average of raw water discharge temperatures was 52 degrees centigrade for rectifier 1, using city water directly, and 47.5 degrees centigrade for rectifier 2, with a heat exchanger. This average 4.5 degrees centigrade difference in raw water outlet temperatures represents the drop through the heat exchanger.

It is seen that each rectifier operated slightly less than one-half of the total time during the year's period, at an average of slightly over two-thirds of its rating. The load was quite steady, and rarely exceeded full load, except for occasional short peak load periods. This is quite typical for street railway substations.

The flow of water to the mercury vapor vacuum pumps was substantially constant, and was also continuous whether the rectifier was in operation or not. For one complete rectifier, it amounted to some seven or eight cubic feet per hour. In arriving at the data in table I, the cubic feet of water was determined by deducting an arbitrary allowance for the vacuum pumps, from the total volume registered by the water meters. For the year's period, the water furnished to the vacuum pumps figures out to be about two-thirds of that supplied for rectifier cooling.

It may seem surprising that the kilowatt-

hours per cubic feet of cooling water are slightly higher for the number 2 rectifier with the heat exchanger. The probable explanation is in unavoidable inaccuracies in the calibrations and readings of the meters, combined with the fact that an arbitrary allowance had to be made for the rather large amount of water taken by the mercury vapor vacuum pumps. Since the water from the unit operating without heat exchanger discharged at an average of 4.5 degrees centigrade higher than that from the other unit, it is obvious that it could not have used quite as much quantity. However, the data indicate that the somewhat greater amount of water required by the use of a heat exchanger is entirely negligible in over-all station consumption, particularly with the low load factor common in railway practice.

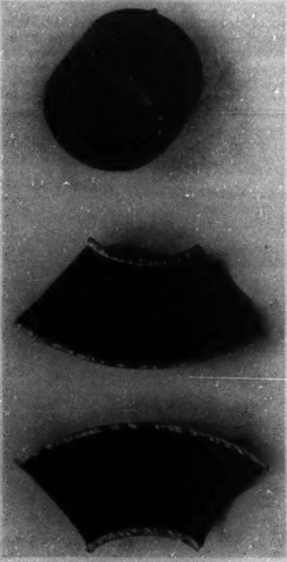

Figure 3. Copper ell removed from number 2 rectifier, after approximately two years' operation with a heat exchanger

At the beginning of the test, the interior of the copper cooling piping at the top of the rectifier section was inspected, by removing the tank thermometer bulb. Both number 1 and number 2 rectifiers had been in operation for about a year at the time this test was started. The interior of the copper piping was found clean with the exception of a light film of a black deposit which could be readily removed with a cloth. An analysis by the city chemist showed that this deposit contained oxides of both copper and iron. A sufficient amount of material was not obtained to permit making a conventional quantitative analysis and determining the relative percentages of these materials present.

In April of 1940, after the test had been in operation for about six months, the tank thermometers were again removed on both rectifiers to examine the interior of the copper piping. On number 1 rectifier, which had been using raw water, the thermometer bulb showed very slight signs of pitting and corrosion, particularly when examined under a microscope. There was a deposit on the thermometer bulbs, and on the interior of the piping, having the appearance and consistency of mud. A chemical analysis of this material indicated the presence of the oxides of iron, aluminum, and copper. On number 2 rectifier, which had been operating conventionally with the heat exchanger, the appearance was the same as on the previous examination at the beginning of the test. This was, of course, to be expected.

At the conclusion of the test, the 90-degree ells in the discharge piping leading from the cathode, were sawed out for inspection and photographing. Figure 2 is a photograph of this ell and the deposit from number 1 rectifier. Figure 3 is a photograph of the ell removed from rectifier 2.

The deposits in the rectifier pipes were similar to those found after six months, except that the amount in number 1 rectifier had increased. The deposit in number 2 rectifier was a thin black film which was very loose and could be easily wiped off. That in number 1 was somewhat harder, but much of it fell off when it became dry. It could all be easily removed, and it should be possible to keep the pipes clean by flushing, at least if some organic solvent is used.

Spectroscopic analysis, which provides approximate quantitative figures was made on the deposit in each rectifier. For number 1 rectifier this indicated the order of 10 per cent of silica, 10 per cent alumina, 22 per cent iron, 22 per cent copper, both iron and copper being in the form of compounds, and 3 per cent organic matter. Number 2 rectifier deposit, much less in quantity, had the same ingredients but proportionately more copper and less than one per cent alumina. The large alumina content in number 1 was probably due to the imperfect performance of the reservoir filter beds, which is mentioned later.

Both the presence of the copper in the deposit, and an examination of the surface of the fitting removed from the number 1 rectifier, indicated some corrosion of the copper. However, the rate indicated was quite slow and there was no evidence of pitting. Practically no corrosion was indicated in number 2 rectifier.

In discussing corrosion and deposition effects, an analysis of the city of Philadelphia water by the Philadelphia city chemist, is of interest. This analysis is given in table II. The recirculated water had a "*p*H" value of 8.3 as compared to a value of 7 for the raw city water used for cooling number 1 rectifier. The cooling water of number 2 rectifier should be slightly less corrosive than that of number 1. This can be explained by the fact that any dissolved gases would be driven off by recirculation, and any inherent acidity of the water would be used up by chemical action. The total suspended matter average of 1.8 ppm is about four to five times what is considered normal and was probably due to constructional work being done at the Queen Lane Reservoir, which prevented maximum efficiency of the filter beds. It would seem, therefore, that the test was conducted under

Table II. Analysis of Erie Substation Water Supply

	September 1939 (PPM)	March 1940 (PPM)
Chlorides	13.6	9.0
Sulphates (SO_3)	97.0	42.0
CO_2	4.0	
Iron	0.07	0.11
Alkalinity ($CaCO_3$)	61.0	28.0
Turbidity	0.5	3.0
Total hardness	161.0	92.0

Total suspended 1.8 ppm average of monthly measurements during year the severest conditions, and the amount of deposit found was probably exaggerated.

It must be remembered that this report covers experience only with Philadelphia city water. Even here, although this experience indicates that obstruction of cooling water passages with deposits could be prevented by periodic flushing and that the rate of corrosion would permit a reasonably long life, greater freedom from maintenance as well as assurance of long life justifies the use of heat exchangers.

C. Van Brunt (General Electric Company, Schenectady, N. Y.): In this paper the subject of the composition of natural waters as affecting the life of a chromate addition is touched upon. I would like to elaborate somewhat on Mr. Remscheid's statements on this point.

There seem to be three main possible sources of consumption of the chromate. The useful consumption, as is stated in the paper, is now believed to consist mainly in a precipitation on the metal of an oxidized iron-chromium complex which constitutes a protective film. This fixation of chromium takes place almost immediately after dosage. We have no data as to how much subsequent destruction and replacement occurs. The main purpose of adding a concentration of chromate which is far in excess of the actual amount fixed upon the iron surfaces, as we do, is to set up a diffusion potential to insure penetration by the solute of crevices and cavities (including preexistent corrosion pits) more or less isolated from stirring influences. Experience has also shown that as is stated in the paper a high content of chloride calls for excess chromate. Since we do not know the exact mechanism of the chloride effect on the protective film we cannot explain this. Our own records do not show any parallelism between chloride content and chromate life. We shall be glad to hear of the experience of others on this point.

The two possible sources of useless consumption of chromate are (1) precipitation as a loose insoluble chromate by metal ions present in the water and (2) reduction of the chromate ion to the chromic ion, which is useless as a corrosion preventive.

Although the first reaction has been observed in other than rectifier installations, a concentration in natural waters of those metals which form insoluble chromates sufficient to cause deposition would be so abnormal as to permit dismissal from consideration here. The second reaction is decidedly more probable. In general it may be said that organic impurity in the water—vegetable matter, bacteria, etc.—or anywhere in the system in the form of contamination on surfaces reached by the solution, is a potential source of loss of chromate. Another possible source of reduction is an imposed cathodic voltage. In both of these the reaction is greatly stimulated by acidity, and, conversely, can be inhibited by a sufficient alkalinity. This is the reason for the advice that sufficient alkali should be added along with the dichromate to convert it to chromate. The limitation to an excess of alkali is fixed in the rectifier application only by the great increase of electrical conductivity of the solution thus produced.

Thus it will be seen that we need not fear the effect of any common mineral impurity in raw waters except possibly chloride on the life of a chromate addition. Organic matter, on the other hand, constitutes a threat which can be minimized by maintaining an alkaline reaction. The observed shorter life of chromate in installations using well water may reasonably be ascribed to its higher content in organic matter combined with an acid reaction, although we have no analytical supporting data in the reported cases.

Mr. Remscheid mentions the dependence of chromate life upon the amount of make-up water added. If this amount measures loss of solution by leakage or spillage the statement is correct. It will be seen from what has been said that loss by evaporation should have no effect unless the added make-up water contributes fresh reducing matter.

The electrolytic test devised and described by Mr. Remscheid for testing adequacy of protection by chromate has given excellent service. But it should be remembered that his observations have been with a limited range of natural waters. It is believed, however, that the test is widely applicable, the only variation in the results with different waters to be looked for is in the visible anode phenomenon he describes. The nature of this will probably vary with the anion composition of the water. The decisive point is the absence of anodic attack.

J. H. Cox (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The sodium dichromate treatment of cooling water, as discussed in Mr. Remscheid's paper, constitutes a completely satisfactory solution of the corrosion problem in the cooling of mercury-arc rectifiers. However, frequently in technical problems, more than one solution is formed, varying in completeness, cost, and complication and the one used depends upon the relationship of these factors to the application.

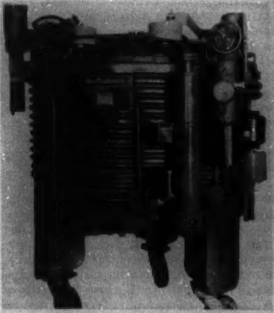

Figure 4. Small multianode rectifier equipped with copper cooling coils welded on

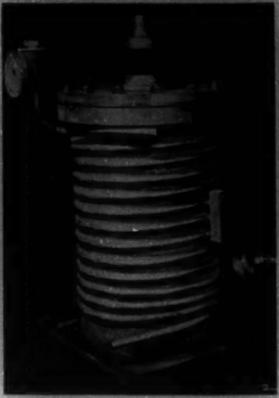

Figure 5. Large ignitron tank with copper cooling coils soldered on

The sodium dichromate treatment of rectifier cooling water involves a number of nuisance factors; namely, the solution is unpleasant to handle, it must be periodically checked and maintained, and it accentuates the problem of electrolysis at the end of the insulating connections to the raw water supply where the rectifier tank is not connected to ground. Obviously, the use of any sort of treated water requires a recirculating system and the use of a heat interchanger. Actually, the use of a closed system with reasonably pure water and without treatment constitutes a practically corrosion-proof system. Oxygen is an essential ingredient in the iron corrosion process. Therefore, if the cooling water is recirculated in a system that is closed to the atmosphere, the only oxygen available is that absorbed in the initial charge and any make-up water. The water jackets of several rectifiers operating with untreated water in a closed system were removed after three

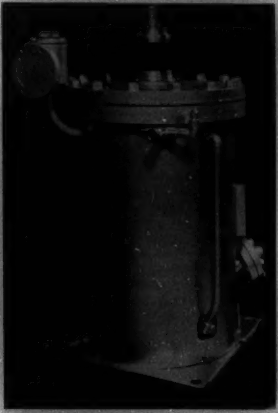

Figure 6. Ignitron tank shown in figure 5. Completed

years of service and the steel surfaces were found to be clean and practically free of corrosion. The rate of corrosion found would indicate a life of at least from 25 to 50 years.

I do not wish to infer that sodium dichromate treatment is not an effective method of corrosion prevention. It is, and I merely want to question whether, for many applications, its nuisance factors outweigh the small degree by which it reduces corrosion over the simple heat exchanger using pure water.

Another complete solution of the corrosion problem is the use of nonferrous cooling provisions. Methods have been worked out for welding, or soldering, copper pipe to the steel walls of a rectifier tank. In designs where the heat density is high, this method has the advantage of superior cooling since the added thermal resistance of the junction of the two metals is more than compensated for by the much greater velocity of the water at the cooling surfaces.

Copper cooling coils can be attached to either large or small tanks, but the difficulties increase with the size of tank. Therefore, the use of copper coils is probably not justified on multianode rectifiers but they work out most attractively on the smaller and simpler tanks inherent to ignitrons.

When equipped with copper cooling coils the only objection to the cooling of rectifiers directly with raw water is the degree to which the water available deposits scale and sediment. Such deposits in rectifier cooling pipes are more than usually objectionable because the pipes are necessarily curved, which precludes mechanical cleaning and deposits must be removed by flushing. Actually the advantage of direct cooling is not great since a recirculating system is necessary in any event to provide proper temperature gradients and control. This recirculating system contains all of the elements of a closed system except the bare heat exchanger, and the inclusion of this item is usually more than justified as insurance from difficulty with scale and sediment.

The following figures show various designs using copper coil cooling jackets.

E. J. Remscheid: In the discussion presented by Mr. Cox he brings to our attention several points in connection with the use of sodium dichromate. These points are of minor importance where the life of apparatus will be actually extended, by the application of an inhibitor. I am in full accord with Mr. Cox in this respect and feel that wherever water is available which will not in a reasonable length of time produce a "corrosion problem," then the application of an inhibitor is unjustified. However, should the "corrosion problem" be a possibility within the expected life of the apparatus, then the addition of a heat exchanger and the application of an inhibitor is low-cost insurance in preventing interruptions in service and expensive repairs.

Mr. Nixon and Mr. Pearce's interesting discussion presents another phase of corrosion in the nonferrous field.

Because of the gradual decay in effectiveness of the sodium dichromate solution as an inhibitor, as explained in Mr. Van Brunt's discussion, periodic examination of the solution is necessary. The frequency of such examination will naturally depend upon the chemical nature of the water, seasonable variation in chemical constituents, and the amount of make-up water added.

It is evident that the use of sodium dichromate is not applicable to all corrosion problems, but it opens up a field of thought whereby all corrosion problems should be studied and a remedy found, so that the expected life of water-cooled apparatus will not be limited by corrosion.

Picture Transmission by Submarine Cable

Discussion and author's closure of paper 41-18 by J. W. Milnor, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 105–08.

W. S. Gorton (Bell Telephone Laboratories Inc., New York, N. Y.): It is gratifying to one who has been connected with the development of submarine cables to learn that submarine cables are now carrying the currents of picture transmission as well as those of printing telegraphy and of the cable code and thus that additional use is being made of the superior stability of the transmission path and the reduced susceptibility to interference offered by the submarine cable. These aspects of the subject have been discussed by the author, and he has given some values of the magnitude of the interference. It would be of much interest if he would give us more detailed information concerning the range between 5 and 500 volts, in view of the connection between cable interference, radio interference and transmission, magnetic storms, and sun spots.[1] It would also be of much interest to know whether the properties of the cable have changed at all in the 14 years since it was laid, and if so in what respect and how much.

J. W. Milnor: The discussion has centered around the stability of the path which is furnished by the submarine cable for picture transmission, and the types of interference to which the path is subject. The static disturbances which find their way into both radio circuits and submarine cables, may be considered to be present at all frequencies between roughly 1 cycle and 10^7 cycles per second. The ocean water tends to shield the cables, so that only the lowest part of the frequency range is of importance. The static currents cause no substantial interference to performance when the working equipment is properly designed to take it into account.

As distinct from the above, the earth potentials which coincide with or shortly follow disturbances in the atmosphere of the sun, are in a frequency range from about one cycle per hour to two cycles per minute, which is well below the operating frequency, but still must be taken into account in the design of equipment. We have learned how to operate cables in telegraph service through the heaviest earth potentials that occur. Picture transmission, however, is impaired when earth potentials are severe.

I know of but one occasion in the past three years when 500 volts was reached, and that continued but a few minutes. Values exceeding 100 volts occurred on 28 different days in that period, the duration of each averaging perhaps 15 minutes. Values of 50 volts occurred more frequently, but they are of less importance.

Since the loaded cable used in this service was laid in 1926 there has been no change in its inductance of amount sufficient to be observed by attendants responsible for equipment or operation of the cable. Measurements of impedance show that the sensitive permalloy loading in some limited sections has suffered changes in inductance, but this has been insufficient to cause noticeable change in the over-all attenuation.

High-Potential Testing Equipment for Quantity Production

Discussion and author's closure of paper 41-55 by C. M. Summers, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 289–92.

J. H. Goss (General Electric Company, West Lynn, Mass.): The author has brought out the major defects of high-voltage short-time testing of low-voltage apparatus that come about in the attempt to speed up the tests.

Many thousands of such test sets have been made and are being used daily, many of which are subject to the criticism of introducing transient surge conditions during the test. While it may not be practical to cover this type of insulation testing in AIEE specifications, it would seem worth while to consider adding a note of warning and to suggest the principles that should be followed in developing such a test. This paper would furnish an excellent basis for such comments or notes.

The use of the cathode-ray oscillograph, as suggested, would be a real addition to many testing sets now in use. Such oscillographs are low in cost, readily available, and give immediate warning of unusual conditions arising during a particular test.

The wave shape in figure 2 is far from a sine wave. While it illustrates the initial surge very well, I should like to ask the author for an explanation of this particular wave shape and just how this oscillograph was obtained.

The point of the effect of conduction current with moist organic dielectric materials in the testing set transformer regulation is well made. This is an excellent example of the additional information that may be obtained from the cathode-ray oscillograph.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): Mr. Summers points out the difficulties of high-potential testing in quantity production. The principal source of trouble appears to be the overvoltages produced by connecting the

Figure 1

test piece through the inductance of the testing transformer to the source of power by means of hand electrodes. I agree with him that oscillations and overvoltages should be eliminated since their frequencies and amplitudes will differ widely depending on the type of test equipment used, the capacitance of the test specimen, the point of the 60-cycle wave at which the test piece is connected, the speed at which contact is established, etc. Therefore, different test results will be obtained on test specimens which are identical depending on the factors which are out of the control of the operator. The author has pointed out a solution to this problem which consists essentially in insertion of series resistance in the circuit of sufficient value to damp out these oscillations.

I would like to suggest another method. The details have not been worked out, but the principle is this:

The oscillations in the usual testing circuit are caused because the charging current of the specimen has to be supplied through an inductive circuit. If a capacitor with a capacitance of approximately 10 to 20 times the capacitance of the test specimen is connected permanently in parallel with the high-voltage winding of the testing transformer, the high charge accumulated in this capacitor will be available at the time of spark between the hand electrode and test terminal causing a voltage drop of only a few per cent. Therefore, current does not need to be supplied through the inductive circuit and oscillations and overvoltages are eliminated.

The voltage measured across a capacitor of 0.0005 microfarad as a test piece with and without the large capacitor is shown in figure 1. It is evident that overvoltages do not exist when the capacitor is connected. In this respect the circuit suggested in this discussion is equivalent to that suggested by the author.

I believe that the circuit with capacitance connected has an advantage because the charge stored in this large capacitance will be available to complete incipient breakdown through the insulation of the test specimen when once started by corona or partial breakdown, since series impedance between the test piece and the source of power supply is a minimum. When tests are made with long leads between the transformer and the hand electrodes, some small amount of resistance (of the order of 100 ohms or less) should be connected between the large capacitor and the test specimen to avoid high-frequency oscillations due to the inductance of the leads and the capacitance of the specimen.

C. T. Weller (General Electric Company, Schenectady, N. Y.): The question as to what constitutes suitable equipment for making high-potential tests has been with us for a long time. It came up in connection with the first edition of AIEE Standard 4 on measurement of test voltage in dielectric tests. The differences of opinion that existed in regard to the measurement specifications were negligible compared with the differences in regard to the testing equipment. Even if the desirability of including test-equipment specifications in a measurement standard were conceded, it would still be impossible to give sufficient details to cover all conceivable conditions. Such details are important, since practical testing experience has shown that voltage measurements made when using unsuitable testing equipment may be very misleading. When the subject of the step-up transformer rating is under consideration, the reaction is apt to be that the smallest unit available should be entirely satisfactory because of the light load; frequently this has meant the selection of a potential transformer. Such a conclusion disregards the possibility of surges due to heavy corona streamers, momentary arc-overs, or switching; the effect of switching surges on the ordinary voltage measurements is clearly shown in Mr. Summers' paper for small apparatus. These surges are even more important for large apparatus, for which the rating of the testing equipment becomes a major consideration. I once saw an attempt made to test all three phases of a 25,000-kva generator with high-potential equipment barely large enough to test one phase at a time. It is probable that no other class of equipment is so universally misapplied. In general, it may be concluded that amply-rated, low-reactance equipment is preferable both for routine and for special high-potential testing.

C. M. Summers: The physical size of a high-potential testing transformer could be fundamentally determined if we had accurate information regarding the amount of energy required to produce a failure. How much energy is required to produce an incipient breakdown and how much more energy is required to produce complete failure? In addition to the energy required for breakdown, the testing transformer must be able to supply all of the charging current and leakage current required by the load and at the same time maintain good voltage regulation. Mr. Weller is correct in his statement that testing transformers should be amply rated or co-ordinated with the load requirement. However, a surplus of capacity in the testing transformer will not alleviate the hazards arising from switching surges, and the large transformer may subject the insulation to more severe stress than a small transformer properly controlled.

Mr. Hagenguth has introduced an interesting alternative method for minimizing the effect of switching both in the high-voltage and low-voltage circuits. This method may have merit in the fact that additional energy can be supplied by the capacitor, but this again brings us the question of how much more energy is required to produce a complete failure than incipient breakdown. Incipient failures have been observed on the cathode-ray fault detector an instant before complete breakdown occurred, particularly when the potentiometer control as described in the paper was used in connection with the testing transformer. There is a growing philosophy that nondestructive high-production testing is the ideal test, providing of course the testing equipment will produce a positive indication of impending failure. In addition to the cost of the high-voltage capacitor required by Mr. Hagenguth's arrangement, a control of the magnitude of the test voltages is desirable, and this is inherently obtained with the potentiometer method.

Perhaps the question of wave form mentioned by Mr. Goss needs further explanation. The wave shown in figure 2 of the paper represents the test voltage only while an arc is established during the high-voltage switching period. This is a typical wave form associated with circuits containing an arc. The actual wave form of test voltage when the high-voltage circuit is solidly established is nearly sinusoidal.

Automatic Printing Ammeter

Discussion and author's closure of paper 41-3 by T. G. Le Clair, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (March section) pages 93–9.

M. S. Wilson (General Electric Company, West Lynn, Mass.): The device described by the author is interesting and ingenious. While it does not furnish as complete information as a recording instrument of the conventional type, it does furnish sufficient information for the purpose required in a more compact and convenient form.

It is indicated in the paper that an accuracy of plus or minus one per cent is obtained. From the description it would appear that the current is balanced to within 1 ampere which would be one per cent assuming a full scale of 100 amperes. If, however, the maximum current does not exceed 10 or 20 amperes in some of the circuits, the accuracy would be five per cent or less. This is the penalty paid when a single range instrument is used to measure quantities which may vary widely in magnitude, but it still may be satisfactory for this application.

There is one condition of operation about which we should appreciate further information; in the case of a fluctuating load, what would be the result if the current in a particular circuit were 39 amperes, for example, and the 10's selector switch stops at 3, then the current shifts suddenly to 41 as the units selector switch starts to operate? Would the instrument's switch stop at 1 with 31 as the total, or would the 10's switch move up to 4?

There is one point in the totalized readings which is not clear, and that is that it would appear that the readings are simply added up algebraically instead of vectorially. If this is the case a considerable error might, of course, result. For example, if the current in two circuits were balanced but one operating at 0.50 per cent power factor and the other at unity power factor an error of 13.4 per cent would result.

We would appreciate the author's comments on this point. Further information would also be appreciated on just how much difficulty was encountered due to variable resistance in the contacts and if any unusual precautions were taken to keep the contact resistance at a minimum.

Paul MacGahan (Westinghouse Electric and Manufacturing Company, Newark, N. J.): Looking at it from the point of view of an engineer engaged in meter manufacturing, Mr. Le Clair's automatic printing ammeter is of considerable interest. It fills of course a definite need in powerhouses or substations, as explained so clearly by Mr. Le Clair.

The design and construction of such an instrument seems to me to be quite definitely in the province of the operating engineers rather than that of the manufacturer and is an excellent example of how operating engineers can solve their special problems without calling upon a manufacturer.

For a meter manufacturer such a project would be a special job throughout to suit an individual installation, and every additional outfit would be different, involving as it would, a study of each installation, field development, complete manufacturing, and drawings. The expense of preparation would be prohibitive. It would divert effort which could more profitably be applied in other ways.

Special apparatus can be efficiently developed by a meter manufacturer, and thus become "desirable" when it can pay its own way or else project the maker into future desirable activities. Such special apparatus may turn out to be an important standard product later on, as exemplified by the development of oscillographs and telemeters. It is also desirable as a service to the industry when the meter manufacturer has available talent or tool facilities which do not exist elsewhere.

T. G. Le Clair: The statements in Mr. Wilson's discussion concerning the accuracy of the printing ammeter are substantially correct. If the meter is assumed to have a full scale of 100 amperes, the accuracy of this meter compares favorably with the accuracy of a switchboard-type indicating ammeter with any scale from 25 amperes to 100 amperes. For circuits with a maximum current less than 25 amperes, it might be desirable to use a different multiplier. The meter in its practical application uses a secondary current transformer between the metering element and each of the measured circuits. It is a simple matter to apply the correct ratio of secondary current transformer to obtain any desired multiplier for the various circuits.

When the totalizing attachment is used, it is only necessary that the same multiplier be used for all the group of circuits which are to be totalized together. This is not actually a limitation because if we are going to totalize three circuits, two of which have a maximum load of 100 amperes, and the third a maximum load of 10 amperes, a ten per cent error in the reading of the 10-ampere circuit will not disturb the total reading any more than a one per cent error in a 100-ampere circuit. A practical application of this principle would be in the case of a generating station where three or four large units supply 40 outgoing lines. The meter can then be adjusted for one multiplier for the currents on the outgoing transmission lines, and another multiplier for the currents in the generator leads.

The question which Mr. Wilson brought up concerning the reading of fluctuating load calls attention to a feature not mentioned in the original paper. The meter is provided with auxiliary connections to take care of this particular contingency. Using the example that Mr. Wilson mentioned, if the current in a particular circuit is 39 amperes when the tens selector switch stops at 3 and increases to 41 amperes before the unit selector switch operates, the procedure is as follows: the tens selector switch will print the figure 3 as usual while the current is 39 amperes. Before the unit selector switch operates, the current has increased to the point that nine additional amperes in the units coil will not balance the load current. The units selector switch is equipped with an auxiliary contact which will stop the rotation of the switch in the ninth position and print the figure 9 regardless of whether or not the balancing relay has come to the balance point. This feature is, however, seldom called into play. The time which elapses between the balancing on the tens digit and on the units digit is only a fraction of a second and during this time, the current will not vary much on an ordinary circuit.

Mr. Wilson's statement is correct that the totalizing operation in this meter is algebraic and not vectorial. For the normal application to determine the loading of transmission lines, the algebraic addition is an advantage. The thing which determines capacity needed in transmission lines is not the vector sum of the loads on the various transmission lines, but the loads on each of the lines in a given group which cause the heating of cable in each of these lines. In ordinary cases, where parallel cables serve a common load, it is not possible to have a wide variation in power factor on the parallel cables due to the circuit characteristics. Where these cables are supplied through transformers with varying tap ratios, it is possible to have material differences in power factor and for such cases it is particularly important to determine the algebraic sum of the currents as a measure of the loading of parallel lines.

No difficulty has been experienced due to the variable resistance in the contacts of the metering circuit in two or three years' operation. In fact, one of the instruments was dismantled and put together several times for testing and demonstration purposes. After this operation, no recalibration was found to be necessary. The apparent reason for the stability of calibration is due to the fact that the values of the resistances used in the calibration circuit are high compared to the resistance of the contacts.

Mr. MacGahan's discussion refers primarily to the relationship between the manufacturer and user of metering equipment and is a worth-while contribution to this subject. I believe with Mr. MacGahan that there are times when the design and construction of special equipment is within the province of the user of this equipment. This is particularly true when the equipment is suited only to specialized problems of one user and not suitable for use by a wide variety of users. There are additional times when the development of equipment should be undertaken by the user. This may be the case when the problem is such that it is not easy to explain the needs to a manufacturer in such a way that he can sympathetically develop equipment to accurately fulfill those needs without too much lost motion. In such a case, the most effective progress can be made by having the principle tried and proved by a device made in the user's own shop and adapted to his own needs. From this point on, a manufacturer can adapt equipment for wider commercial applications without losing the fundamental benefits. Frequently the manufacturer can also develop equipment from this starting point which will be better in appearance and in performance from that made by the user's own men.

Such was actually the history of the automatic printing ammeter. The original development work was carried out on the property of the operating company. After the results had proved that the development was justified, it was found possible to have a manufacturer equipped for production of finished apparatus turn out a better and more useful product at no higher cost. By this means, it was also possible to obtain a device which has a broader usefulness and can be applied to a number of problems in addition to the original one which caused the operating company to undertake the problem.

Magnetic Fields in Watt-Hour Meters; Effects of Wave Form on the Registration of Single-Phase Watt-Hour Meters

Discussion and authors' closure of paper 41-43 by C. A. Keener, M. A. Faucett, and M. S. Helm, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (May section) pages 202–05.

M. G. Lloyd (National Bureau of Standards, Washington, D. C.): It would be of some interest to compare the performances of the watt-hour meters of today and those of a previous generation, with respect to the effect of wave form upon their registration. An investigation carried on at the National Bureau of Standards nearly 40 years ago[1] dealt also with single-phase meters of the induction type and applied the third harmonic to produce peaked and flat-topped waves having distortion factors of 10, 24, and 45 per cent. Voltage and current waves had the same form; the load was 100 per cent; and the power factor was kept near unity. Hence no comparisons are available at lower power factors, at different loads, nor with different wave forms for current and voltage. Both investigations applied a third harmonic at different phase angles to distort the wave.

Unfortunately very few comparisons can be made, for although many conditions of the two investigations were identical, the authors of the present paper appear to have given only a few selected results in figures 6 to 10; and for most of these the conditions differ in some items from the former investigation.

In figure 6 with sine voltage and distorted current, the errors are less than 2 per cent up to 40 per cent distortion factor; within 3 per cent up to 65 per cent distortion factor; and become large above 90 per cent.

In figure 7 with sine voltage and 40 per cent distorted current, there is a plus error up to 1.3 per cent for a flat wave. Rosa found no such change with shift in phase when both voltage and current were distorted.

In figure 8 with sine voltage and peaked current, the minus error at unity power factor is changed to a plus error at low power factors.

In figure 9 both voltage and current were distorted (peaked); here the minus error decreased as load increased. At full load, the error is minus 3 per cent for a distortion factor of 50 per cent, compared with only 1 per cent when the current alone is distorted (figure 6). This shows the effect to be multiplied if both waves are distorted, at least for one individual meter (number 1). Comparing this with Rosa's results at 45 per cent distortion factor, meter number 1 is no better than the meters of 1904, and is indeed more affected by wave distortion than three of the 1904 meters.

Figure 10 deals with inductive loads and is not comparable.

1. **Rosa, Lloyd, and Reid.** *Trans. Intern. Elect. Congress*, St. Louis, 1, (1904) page 555; *Bull. of Bur. Stds.*, 1 (1905) page 421.

Warner T. Smith (USDA, Rural Electrification Administration, Washington, D. C.): The authors of this interesting paper have presented the results of their investigations of important characteristics of watt-hour meters. In extensive systems of the REA type, the effect of harmonics on metering instruments is of unusual interest because resonant conditions on the system, in many cases, accentuate the importance of the harmonic voltages and currents relative to the fundamental.

In a situation recently encountered, in connection with an inductive co-ordination problem, values of currents and voltages were measured at the substation as shown in table I.

Table I

Frequency in Cycles Per Second	Primary (Volts)	Per Cent of Fundamental	Primary Current (Milliamperes)	Per Cent of Fundamental
60	7,270	100	10,133	100
300	827	11.5	11,266	111
420	173	2.4	3,153	31

At the time of the measurements, the power factor of the fundamental voltage and current was approximately 80 per cent leading. The power factor of the harmonics was not determined, nor, was the phase angle between the fundamental and harmonic voltages and current. I would like to ask the authors if their investigations covered situations comparable to that shown by the data, and if so, what effect on the registration could be expected?

L. A. Doggett (The Pennsylvania State College, State College, Pa.): In a long series of three-phase tests of several makes of polyphase watt-hour meters in 1927–29, using impressed voltages consisting of sinusoidal fundamentals with and without fifth harmonics, the following conclusions were reached:

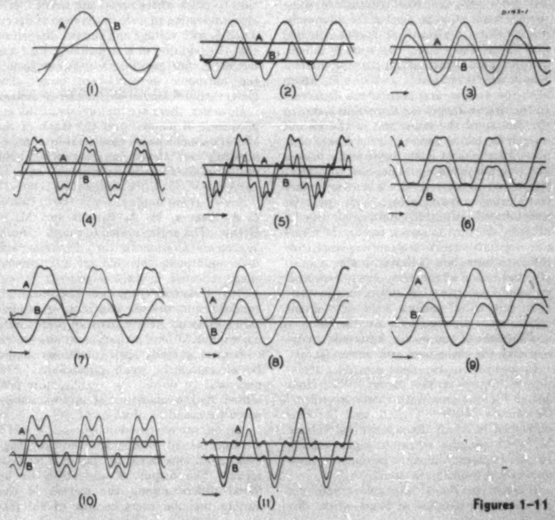
1. For a light-load to full-load range of currents in phase with the fundamental frequency voltages, the greatest error disclosed was less than two per cent; without fifth harmonics;
2. For a similar range of inductive and capacitive loads the greatest error was less than $3^{1}/_{2}$ per cent; without fifth harmonics;
3. When the voltage consisted of a fundamental and a 50 per cent fifth harmonic, the largest error for inductive loads was 9 per cent, whereas for capacitive loads the errors were in all cases very large and of the order of magnitude of 20, 40, 60, and even 100 per cent slow.

In one of our tests harmonic-free voltages were applied to a three-kilovolt-ampere, three-phase transformer, delta-connected primary, wye-connected secondary. A load of six two-kilovolt-ampere capacitors in various series and parallel arrangements was connected to the transformer secondary. Using calibrated indicating wattmeters as standard instruments, these loads were metered by two makes of three-phase watt-hour meters simultaneously. Errors of slow 7 to 8 per cent for one meter and fast 12 to 18 per cent for the other were found.

The results presented in this paper and in the discussion by Mr. W. T. Smith show that the watt-hour meter of today has still smaller errors in the cases they describe. The case of capacitive load, however, does not receive sufficient consideration. It is the capacitive load that magnifies the harmonic effects and exaggerates the fifth harmonic or 300-cycle currents. It is only fair to give the watt-hour meter credit for a high degree of accuracy in metering all ordinary loads and many unusual loads. There is, however, some danger in establishing for the watt-hour meter a reputation for universal accuracy since in the case of capacity loads and distorted voltages the watt-hour meter is definitely not reliable. Whenever a buyer of electrical energy is not sure of the accuracy of his watt-hour meter because his load is predominantly capacitive, he may check his meter very easily by the use of standardized indicating wattmeters and a stop watch.

H. E. Trekell (General Electric Company, Lynn, Mass.) and **G. F. Gardner** (nonmember; General Electric Company, Schenectady, N. Y.): In handling this involved problem of the effect of abnormal wave forms on watt-hour meters, there are many features which may be considered. In their treatment, the authors are to be commended, for many of the limitations have been evaluated and the good performance established without a surplus of less important details.

From our experience in measuring the flux in watt-hour meters and observing the voltages induced in search coils placed in the air gaps, we do not believe that the wave shapes shown in figures 3, 4, and 5 are representative of modern meters. The waves shown by the authors, in their oral presentation, show somewhat less distortion.



Figures 1–11

Table II

Figure	Load Conditions	Per Cent Harmonic Content of Voltage Wave, Harmonic Order				Per Cent Power Factor = 100 × Watts / Volts × Amperes	Per Cent Distortion Factor		Per Cent Effect on Watt-Hour Meters (Referred to Registration With Sine-Wave Conditions)	
		1st	3rd	5th	7th		Voltage Wave	Current Wave	Single-Phase Meter Type I-30	Polyphase Meter Type V-3
1	Half-wave rectifier. Sine-wave voltage					63	0	38	+0.4	
2	Saturated reactor. Sine-wave voltage					50	0	37	+1.2	+1.9
3	Fluorescent lamp installation. Sine-wave voltage					97	0	11	−0.1	0
4	Extreme distortion of voltage wave. Resistance load	100	4	13	4	100	14	14	−0.5	0
5	Same as figure 4 except with resistance and capacitance load	100	4	13	4	73	14	54	−1.1	−0.9
6	Less distortion of voltage wave. Flat-topped wave with resistance load	100	10	6	2	100	12	12	0	+0.1
7	Same as figure 6 except with resistance and inductance load	100	10	6	2	50	12		+0.3	+0.4
8	Same as figure 6 except with peaked wave	100	10	6	2	100	12	12	−0.3	−0.3
9	Same as figure 8 except with resistance and inductance load	100	10	6	2	50	12		−0.4	−0.1
10	Flat-topped wave and 50 per cent distortion with 3rd harmonic. Resistance load	100	58			100	50	50	−1.9	+0.3
11	Peaked wave and 50 per cent distortion with 3rd harmonic. Resistance load	100	58			100	50	50	−2.9	−1.4

DESCRIPTION OF LOAD CONDITIONS

In each of the figures. *A* identifies the voltage wave and *B* identifies the current wave.

For figure 1, the current is that supplied to a step-down transformer and a gas-filled half-wave rectifier tube.

Figures 4 and 5 are examples of extreme distortion in the voltage wave of a power system. It is believed that distortion as severe as this is not often found. However, a recent case with 12 per cent fifth harmonic before correction was the subject of AIEE paper 41-74 entitled "System Lower Harmonic Voltages—Methods of Calculation and Control by Capacitors" by Messrs. Feaster and Harder.

Figures 6, 7, 8, and 9 are examples of less distortion in the voltage wave. The values are based on the maximum harmonics reported in Engineering Report No. 15, "Wave Shape Survey on Operating Power Systems" by National Electric Light Association and Bell Telephone system, February 3, 1932.

Figures 10 and 11 show the extreme distortion required to obtain a 50 per cent distortion factor with the third harmonic.

Although some distortion should be expected because of the use of magnetic materials, it is apparent from the actual performance of modern meters that the effect is secondary.

In considering the significance of this problem, the General Electric Company has from time to time considered some specific loads and the data obtained may be found helpful. This work has been divided into cases where first, the voltage is substantially not distorted but the load draws a nonsinusoidal current; and second, where both the voltage and current are distorted. In the first instance, the distortion is due to the nature of the load, and in the second case, it is due to factors in the power supply. In the tests both single-phase meters and polyphase meters connected as single-phase meters were used. Therefore, when considering polyphase meters, it must be remembered that additional factors may be present, due to the power factors at which the respective electromagnets operate, but the data found are believed to give a valuable indication of the errors to be expected. In table I are given the effects on the watt-hour meters of various load and circuit conditions. Also included are references to oscillograms of the waves, harmonic analyses, and the distortion and power factors.

In addition to the tests described attention is invited to the paper, "Watt-Hour Meter Performance With Power Rectifiers" by Messrs. Weller, Trekell, and Stebbins published in AIEE TRANSACTIONS, volume 59, 1940 (August section), pages 449–56. In this instance, the error in the watt-hour meters was found to be small.

Because of these favorable results on outstanding examples of loads where distortion exists, the conclusions of the authors are confirmed and furthermore, it may be said that considerable distortion must exist before significantly large errors occur. It is believed that very rarely does the distortion factor exceed 40 per cent which limits the practical occurrence of distortion to cases where errors are small. It is also interesting to note in the case of figures 4 and 5, with voltage and current distortion, that the addition of a capacitance load had but little effect on the meters even though the harmonic currents are large. The meters still responded well as energy meters.

However, there are limitations in the applications of meters, and the work of the authors should be of considerable value in pointing out those instances where the errors are likely to be excessive.

C. A. Keener, M. A. Faucett and M. S. Helm: The authors wish to thank Messrs. Trekell and Gardner for their discussion and data confirming the findings and conclusions reported in this paper. It is suggested, however, that since the magnetic conditions in the air gap of a watt-hour meter differ so greatly between points only a few hundredths of an inch apart any search coils used to study such conditions should be of extremely small dimensions. The one used to obtain the oscillograms presented had a diameter of approximately seven thousandths of an inch.

The curves presented in figures 3, 4, and 5 are from actual oscillograms showing magnetic conditions in the air gap of a modern meter. The degree of distortion to be found differs among the meters of the various manufacturers because of the differences in the details of the magnetic circuits, especially those parts that operate at high magnetic density under heavy load.

We agree with the conclusions drawn by Mr. Doggett from his tests. However, in comparing results, care must be taken to keep separate the effects of "leading power factor" and those introduced by the harmonics. No particular study was given cases of fundamental current leading fundamental voltage since it was considered unlikely that such commercial loads would be metered individually. The condition does, however, introduce additional factors of interest and warrants investigation. In polyphase meters such conditions, on a single meter element, will not be uncommon and in the study of such meters must be considered.

It is interesting to note the comparisons offered by Mr. Lloyd. We wish to make clear that figure 7 is for conditions of distorted current only, the potential being sinusoidal. In the discussion of figure 9 mention was made of the absence of appreciable differences in the effects of peaked and flat-topped waves when both potential and current were distorted. Both cases appear to offer reasonable checks with the findings of Rosa. One conclusion that might be drawn from the comparisons given is that the addition of corrective details for overload, temperature change, and other errors has not improved the over-all performance of the meter under every possible condition. This is to be expected.

Mr. Smith has raised a question that is difficult to answer quantitatively for the case cited. As stated in the reply to Mr. Doggett, no particular study was made for capacitive loads giving different degrees of distortion in potential and current. It is believed however that, for a case with a degree of distortion as large as that given, and for a customer whose load was a significant part of the total, the use of indicating instruments of the dynamometer type in the calibration of the meter would be advisable. The registration characteristics of the meters involved being unknown it is difficult to predict the result. If the excessive distortion given occurred only at light load, the error in the total registration would probably be small.

The Detection of Initial Failure in High-Voltage Insulation

Discussion of paper 41-27 by J. B. Whitehead and M. R. Shaw, Jr., presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 267–72.

Vol. 60
1941

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The device described by the authors and the results which they have obtained to date, indicate that they have a very useful tool which is likely to elucidate many of the mysteries of cable behavior.

It is well known that a drained cable, that is a cable which has been impregnated with oil and from which the oil has been allowed to drain out, will ionize at a certain critical stress, but if that stress be continued the ionization will stop and will not be resumed until a considerably higher stress is applied.

The reason for this rise in the ionization point is not fully understood. This new instrument might be used to find out something about what is happening inside of the cable while the ionization is dying out.

H. H. Race (General Electric Company, Schenectady, N. Y.): Through operating experience in the field and many types of experiments in the laboratory we are continually learning more as to why liquid impregnated dielectrics behave as they do. In this paper Dr. Whitehead has presented more evidence in support of the conclusions of many investigators that at abnormally high gradients, ionization or localized corona starts in an oil space and if the voltage is maintained, progressive carbonization leads to failure in a few hours.

There are four aspects of this failure mechanism which I should like to emphasize.

First—For any given composite dielectric system there is a voltage threshold value below which ionization will not start. If this voltage is not exceeded and if the physical conditions of the system do not change, the electrical life will be long and final failure will result from slow thermal decomposition or chemical deterioration. This is the desirable service condition and explains the superiority of the oil-filled cable system, which is designed to prevent ionization under operating conditions.

Second—There are conditions under which *failure will not occur even though ionization or localized corona does exist* in portions of the composite dielectric. I believe it is necessary to differentiate between two degrees of ionization: (*a*) one in which the intensity of the corona is too low to cause appreciable thermal decomposition of the surrounding material, and (*b*) spark discharges of sufficient intensity to propagate themselves by carbonization of the surrounding material. The failures in Dr. Whitehead's specimens come in this latter class. On the other hand, it is known that solid-type cables have operated indefinitely with localized corona between layers of paper throughout the insulation wall, as evidenced by wax formation. Apparently the intensity of such discharges is limited, by the amount of energy which can be fed through the capacitance of the portions of dielectric in series with them, to a value too low to cause carbonization and progressive failure.

Third—The greatest danger in abnormal voltage relatively short-time life tests lies in the subconscious tendency to believe that the system which stands up best on such tests will also be best under considerably lower voltage service conditions. In homogeneous dielectrics this may be true but in composite dielectrics it may not, because in long-time service factors leading to chemical change and thermal deterioration may be more important than the physical conditions which determine the ionization starting point.

Fourth—The real contributions of work such as Dr. Whitehead has reported are: (*a*) Improved methods for the study of ionization starting points. (*b*) New knowledge as to the effects of short-time high-voltage applications on oil-impregnated paper together with indications of recovery or self-healing tendencies if the voltage is lowered before material damage has been done.

I hope Dr. Whitehead will greatly extend our knowledge of the latter by a continuation of these studies with corona detection equipment.

Electrolytic Process of Scale Removal From Steel

Discussion and author's closure of paper 41-77 by H. W. Neblett, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (June section) pages 294–6.

F. O. Schnure (Bethlehem Steel Company, Sparrows Point, Maryland): This electrolytic process was added in order to increase the pickling capacity for strip steel of thin gauge, narrow width, and of considerable length, without making a major capital outlay for another line. It appears to be successful.

The first thought in considering this application is that the maintenance required on the additional electrical equipment described, must be considerable because of the bad conditions under which it must operate. Strip steel in a pickle line is in motion only about 50 to 55 per cent of the time, the remainder being employed in threading, welding, tacking, and handling. Consequently, a given increase in the feet per minute speed of the steel while in motion, only results in about half that increase in over-all production. If this electrolytic equipment presents extra maintenance of any consequence, the improvement may not be worth while.

It would seem that the electrolytic features of this addition to the pickling process would always be a nuisance from the maintenance viewpoint and that the increased capacity, although practicable by the method described, might as well be achieved by other means, possibly the addition of another tank in the line.

H. W. Neblett: The comments regarding maintenance are well taken. That part of the equipment that is subjected to sulphuric acid has to operate under severe conditions and the materials that stand up in this service are limited. However, as pointed out in the article, satisfactory materials were found from experimentation. These materials, such as carbon, Pyrex glass, and certain grades of synthetic materials are not affected by acid or electrolytic action and have long life in service free from repair.

The equipment outside the tanks is standard in design and consists of transformers, control, and connections. Therefore, the maintenance on the entire electrolytic equipment as now designed is no greater than any other standard equipment.

The question raised regarding the time consumed in feeding coils to the pickling line including threading, shearing, and welding has to be considered in determining the maximum speed at which any line is to operate. This point is discussed under the heading "Operations."

It is important that a pickling line be so designed that continuous operation of the strip through the pickling tanks can be obtained. This is provided by a looping pit or storage at the feeding end of the pickling tanks, between the tanks and the threading, shearing, and welding equipment. This permits the pickling line to be operated continuously, being supplied with steel from the looping pit during the time a new coil is being handled, sheared, and welded. This permits the strip steel to be in motion continuously through the tanks, which is desirable to prevent the steel becoming overpickled.

Large Electric-Arc Furnaces—Performance and Power Supply

B. M. JONES
MEMBER AIEE

C. M. STEARNS
NONMEMBER AIEE

ELECTRIC arc furnaces are desirable loads for power systems, and are becoming more and more used for producing high-grade alloy steels, as well as for other types of steel. The authors believe that the data in this article will be of value and assistance to others in the solution of similar problems.

It is necessary in connecting large electric arc furnaces onto power systems that it be done in such a manner that neither the voltage changes, caused by the violent and rapid load swings of these furnaces, will interfere with other load of the furnace customer nor be permitted to reflect back into the system in such a manner as to interfere with service to adjacent customers. Also precautions must be taken so that such widely fluctuating loads will neither interfere with the operations of any of the equipment on the power system nor interfere with any interconnection with adjacent power companies. Further, precautions must be taken so that voltage regulation caused by large short-time loads will not be too great.

Summary

In March 1940, a 25-ton Heroult 3-phase electric arc furnace using a 10,000-kva furnace transformer was connected to the Duquesne Light Company system, and in August 1940, a second furnace duplicating the first was installed at the same location. These installations were made by the Pittsburgh Crucible Steel Company at their Midland, Pa., plant near Pittsburgh.

It was believed that the load swings on the first furnace with the accompanying voltage changes would exceed the standards which the Duquesne Light Company had established for this type of load, viz.

Figure 1. Diagram of power system showing 66-kv lines and power stations

Each line on diagram represents two 50,000-kva lines unless noted. Duquesne Light generating capacity is 504,000 kw with a 60,000-kw unit scheduled for service in July 1941

All lines are double-circuit unless noted by (1) or (3)

The 400-ampere 66-kv fuses provide protection for high-voltage and low-voltage faults

---

Paper 41-40, recommended by the AIEE committee on electrochemistry and electrometallurgy, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted October 8, 1940; made available for preprinting December 10, 1940.

B. M. JONES is division engineer of system planning and development department, and C. M. STEARNS is subsection engineer of the Duquesne Light Company, Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

1.5 volts (115-volt base) for the 66-kv system with fluctuations from 3 per hour up to 15 per minute. Precautions were taken in the design of the furnace transformer to include separate reactance to reduce the load swings. Subsequently, it was found that this additional reactance was not eneded and it was removed, thereby improving the operation of the furnace.

The load swings and accompaning voltage changes, after disconnecting the reactance, due to the operation of the first furnace, slightly exceeded the Duquesne Light Company standards. However, no complaints have been received from adjacent customers nor have any difficulties arisen from excessive operation of 4-kv distribution regulators, operation of the power stations, or interconnections.

Second Furnace

Arrangements were made initially to interlock the controls of the two furnaces in such a manner that the furnaces would not melt down simultaneously. Thus the voltage flicker would not exceed that caused by the initial furnace and the regulation would be increased only a small amount.

Following the installation of the second furnace, a test was made with both furnaces melting down simultaneously at the highest secondary voltage. Instead of the load swings of the two furnaces being additive, the swings were diversified to the extent that the net swing of the two furnaces increased only 20 per cent over that of the first furnace. Voltage disturbances increased in the same ratio. In addition, the test showed that the resultant combined swings of the two furnaces were less frequent than for the first furnace alone. Thus the interlocking scheme may not be necessary except as a means of reducing the 15-minute demand.

Method of Approach

This article contains a rather complete treatise of our investigations and presents the industry with these data which the authors hope will be of some use to others in the solution of their furnace problems.

Some data have been published on electric furnace performances and the power system supply (see bibliography), but for the first large installation on any power system the authors strongly recommend getting all data that they can possibly lay their hands on, and making a thorough analysis of them.

Obviously, the correct engineering approach is to determine in advance what the kilovolt-ampere swing and resultant voltage flicker will be, and to provide a suitable system connection with corrective equipment if necessary, to keep the voltage changes within tolerable limits. However, this is not always so easy, for in some cases it is difficult to find out just what the electric performance of the furnace will be.

In addition to the determination of instantaneous load changes, the maximum loads which exist for several seconds at a very poor power factor, and which occur several times during a heat, should be determined. These large loads may result in undesirable voltage regulation on the customer's supply bus or at adjacent customers.

There are many factors involved, and many calculations to be made, not only for normal system conditions but also for the abnormal system condition of reduced capacity, lines out of service, generators off the line, etc. These abnormal conditions may result in voltage disturbances beyond standard voltage limits. However, it will probably not be economical to reduce the voltage changes to standard limitations with lines and equipment out of service because of their infrequent occurrence.

Calculations

Having decided upon the maximum instantaneous furnace load swings, the voltage flicker at the customer's supply bus should be determined from the known or estimated system impedance at that point. The voltage flicker, then, at the nearest customer or substation should also be determined.

The per cent system impedance to the Pittsburgh Crucible Steel Company 66-kv bus in 68-kv terms and on a 10,000-kva base in $R+jX$ terms is:

$(1.1+j4.0)$ per cent

The reactance of each of the 66/11-kv 9,375-kva transformer banks supplying the furnace transformers is 6.0 per cent on a 10,000-kva base. The system impedance is based upon all generating units and all 66-kv lines in service and the West Penn Power tie closed at Colfax.

As the furnace load swings are generally at a very poor power factor, the use of system reactance at the customer's bus will give fairly close results. This system reactance is that ordinarily determined by a short-circuit study. However, the true power does change considerably and if this change and the change in the reactive power are known, then the calculations of the voltage change based upon system impedance rather than reactance will give more accurate results.

The calculations for voltage regulation may be made in substantially the same manner, as described above for voltage flicker.

Application of Corrective Equipment

If the voltage changes calculated as described under the preceding heading

Figure 3. Photograph of power-supply substation—66/11 kv, 18,750 kva—at Pittsburgh Crucible Steel Company, Midland plant

Incoming 66-kv line at left and 11-kv circuits to furnace transformers at right. Lightning arresters mounted at high-voltage transformer bushings

Figure 4. Photograph of charging side of a 25-ton Heroult three-phase electric-arc furnace at Pittsburgh Crucible Steel Company, Midland plant

exceed the allowable values, then corrective equipment should be applied. Discussion here will be limited to correction obtained by synchronous condensers. This as well as other methods of correction have been described by earlier papers, see item 1 in bibliography.

As far as very frequent instantaneous furnace load changes are concerned, the condenser will draw additional leading reactive current to offset some part of the additional reactive furnace load. For a general analysis, it can be considered that the system and the condenser will share the increased furnace reactive load in proportion to the inverse of their respective reactances. Thus the reduction in voltage flicker may be estimated as well as the amount of corrective capacity to obtain the desired reduction.

The condenser can be made to draw more leading reactive current by increasing the system reactance. This may be done by installing a buffer reactor in the furnace supply circuit ahead of the condenser. Actually, this buffer reactor produces increased voltage drop at the terminals of the condenser thus causing it to draw more leading reactive current. The condenser will draw increased leading reactive current in proportion to its subtransient reactance. Thus the speed of condenser field has very little to do with the correction of very rapid furnace reactive changes. Speeding up the field will, however, materially improve regulation for large load changes which last for several seconds.

Duquesne Light Company System and 66-Kv Supply to Furnace

Figure 1 shows the Duquesne Light Company system, including generating stations and the 66-kv transmission ring. The two major sources of interconnections with adjacent utilities are shown, one at Colfax with the West Penn Power Company and the other at Valley substation with the Pennsylvania Power Company. The latter is normally open, but in emergency can be closed and operated in parallel with the other systems, the 40,000-kva regulating transformer between the two systems being able to control both true power flow and reactive flow, the latter providing voltage regulation at this point, see items 6 and 7 in bibliography.

A single 66-kv circuit, ACSR 336,400 circular mils (4/0 equivalent) tapped to the single circuit between Ambridge substation and St. Joseph lead substation, was extended nine miles on wood poles with two ground wires to the Pittsburgh Crucible Steel Company at Midland, Pa. There is an extra degree of insulation and ground protection built into this extension which will make it practically immune from insulation troubles.

Supply Substation

Figure 2 shows the supply substation schematically for the 2 25-ton Heroult furnaces. Figure 3 shows the photograph of the substation with 2 9,375-kva transformer banks and one single-phase spare unit. Normally, each bank supplies one furnace independently and the 11-kv bus tie disconnecting switch is closed only in case one bank is out of service. At this time the furnace must be operated at a reduced secondary voltage to keep the load on the one 9,375-kva bank within its limit.

**Calculated on basis of average amperes per phase and AB voltage.

†Power factor from charts using A amperes and AB and CB voltage.

General: The average power factor for loads during the refining period varies between 85 and 95 per cent. Inst. change—instantaneous change.

GRAPHIC METER RECORDS

Graphic records were obtained of customer's 11-kv voltage, furnace reactive kilovolt-amperes, kilowatts, amperes in each phase and single-phase power factor, and 66-kv voltages at the nearest attended substations. Sections of these charts during different periods of the heat are shown in figures 6, 8, 10, 12, and 13. These charts were run at approximately six inches per minute speed.

The seven meters at the furnace were driven by a common shaft and a switch was installed to short circuit the current transformers and open the potential leads simultaneously. This switch was operated at 15-minute intervals to aid in synchronizing the charts for analysis purposes.

In order to run the charts at high speed, most of the damping effect is eliminated. This undoubtedly allowed the meters to overswing.

OSCILLOGRAPH RECORDS

An oscillograph record was taken at several points during the heat. Portions of these records are shown in figures 7, 9, 11, and 14. The record of the single-phase wattmeter is intended to show the rapid changes in furnace consumption and not the true single-phase load, in so far as the single-phase wattmeter is 30 degrees out of phase with three-phase balanced loads.

It is almost impossible to obtain oscillograph records of the maximum loads or changes in loads because of their short duration.

Results

Table I shows various values obtained from the graphic charts of kw, reactive kilovolt-amperes, amperes, volts, and power factor. These values are instantaneous ones taken during maximum furnace load swings or furnace loads. Several of the numbered points are shown on the exhibits.

The maximum instantaneous furnace load swing, lasting a fraction of a second, amounted to 8,600 kva, 3 phase with a calculated power factor of 54.5 per cent (change in load). An analysis of the load swings indicated that the maximum occurred only once and only ten exceeded 7,000 kva during the heat.

The maximum instantaneous load of seconds duration, was found to be 14,400 kva or 144 per cent of the furnace transformer rating.

Based upon maximum load swings (8,600 kva) the voltage flicker at the nearest 66-kv customer (St. Joseph Lead Company) amounts to 2.3 volts, at Valley substation, 2.1 volts, and at Ambridge substation, 1.8 volts. See figure

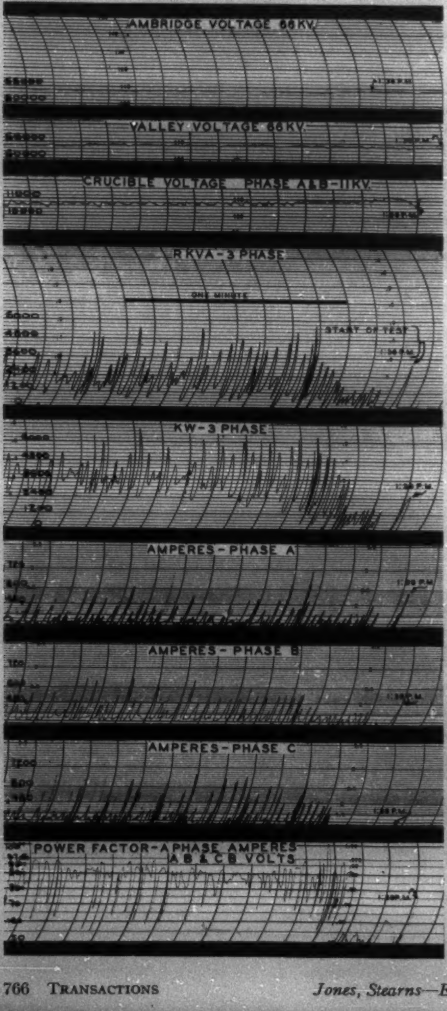

Figure 6. Graphic charts at start of heat at 1:38 p.m.

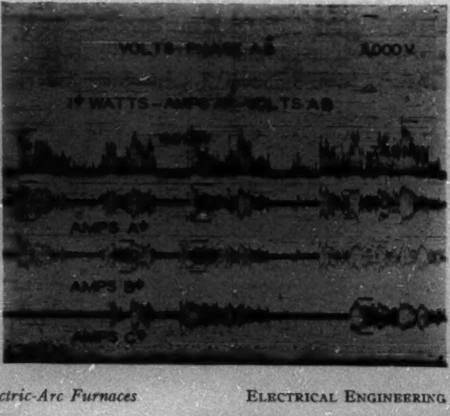
Furnace swings occur approximately once a second

Figure 7 (below). Oscillograph film at start of heat

A single-phase arc struck and restruck ten times in the space of 15 seconds before all three phases struck. After this initial period, all three phases struck and restruck ten times with currents in all three phases fairly well balanced before the arcs became generally stable. A portion of this performance is shown on this figure



1 for locations. However, due to the fact that the majority of the load swings were considerably less than the maximum, no complaints have been received from adjacent customers and no difficulties have arisen from excessive operation of 4-kv distribution regulators or in the operation of the power station or interconnections.

Thus perhaps corrective equipment should not be installed to correct for the maximum swing but for something less than the maximum, assuming that a few voltage changes in excess of the standard could be allowed.

The location of the furnaces at the end of a long line and with considerable impedance to the supply bus, probably accounts for the fact that the load swings and maximum loads are less than might be expected from a furnace of the size installed.

Due to the fact that no other customers are located near the furnace installation the voltage flicker and regulation at the customer's 66-kv bus are allowed to exceed values that would normally be allowed and the voltage changes at the nearest customer are materially less due to the relatively high impedance between it and the furnace 66-kv bus.

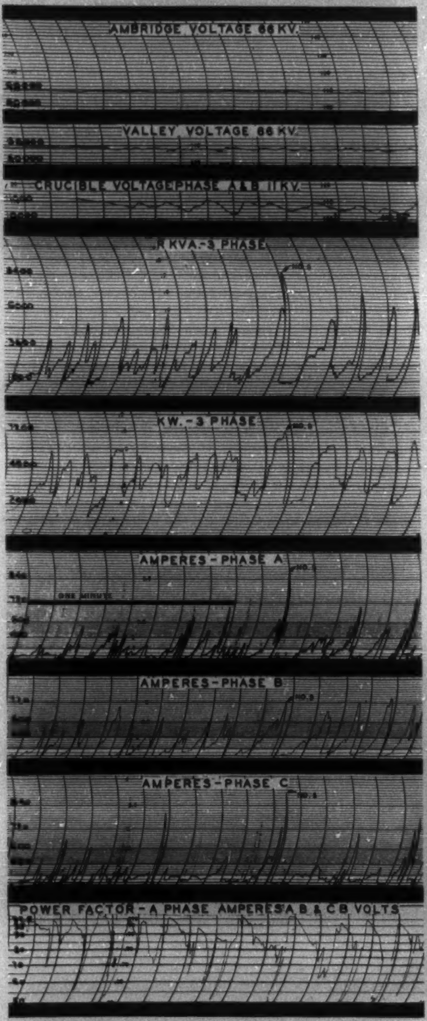


Figure 8. Graphic charts taken 14 minutes after start of heat

The swings have become less frequent, but are greater than shown on figure 6

Complete heating cycle 6 hours and 15 minutes.

Figure 9 (below). Oscillograph film taken 14 minutes after start of heat

The currents have become more stabilized than in figure 7. The arc did not completely go out during the film

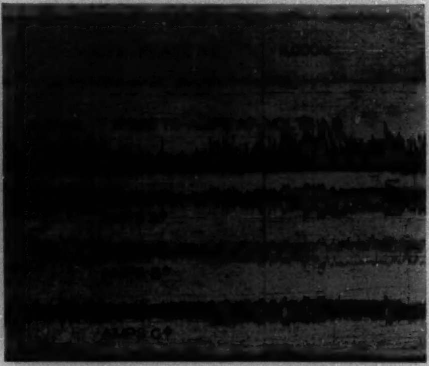

Table II shows the 15-minute kilowatt demand during each 15-minute period of the heat. The maximum demand of 8,400 kw is at approximately 85 per cent power factor or 9,900 kva. Subsequent to this test and prior to the installation of the second furnace the 15-minute demands were somewhat less.

The oscillograms showed maximum amperes of 840 while the graphic charts gave maximum values of 1,100. Probably the true maximum lies between the two, in so far as the graphic meters would probably overswing and the maximum values were probably not recorded on the oscillograph film.

Test on Two Furnaces

Following the installation of the second furnace, test data were obtained of the two furnaces melting simultaneously at the highest secondary voltage. Graphic meter chart records only of voltage, amperes, etc., the same as for the first furnace were obtained. Time has not permitted the preparation of the exhibits for inclusion in this paper but they will be available at a later time for discussion purposes.

During the test, number 2 furnace was melting the initial charge and number 1 furnace was melting the "back charge." Number 2 furnace started the initial melt down 29 minutes prior to number 1 furnace starting the melt down of the "back charge." The test continued from the time number 2 furnace started the melt down of the initial charge until the initial charge was melted, approximately $1^3/_4$ hours. The 11-kv bus tie was closed during the test to facilitate the obtaining of the records.

Results

The maximum combined instantaneous load swing of the two furnaces, lasting a fraction of a second, amounted to 10,580-kva, 3 phase with a calculated power factor of approximately 52.0 per cent (change in load). The next largest swing amounted to 7,500 kva, 3 phase and all other swings were materially less than 7,500 kva.

The maximum instantaneous load of seconds duration was found to be 22,850 kva, and there were several near this value.

Based upon maximum load swings (10,580 kva) the voltage flicker would exceed that of one furnace by about 20 per cent. However, the combined load swings of the two furnaces were much less frequent than for one furnace and actually there seemed to be no flicker

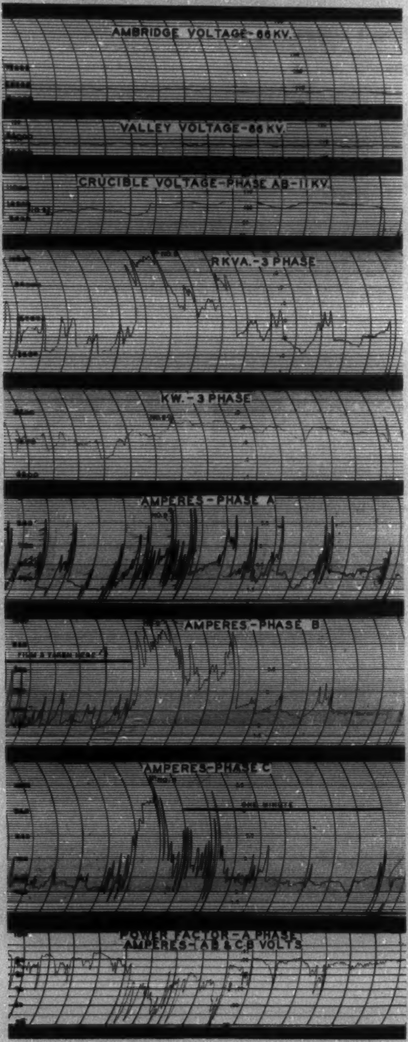

Figure 10. Graphic charts one hour after start of heat

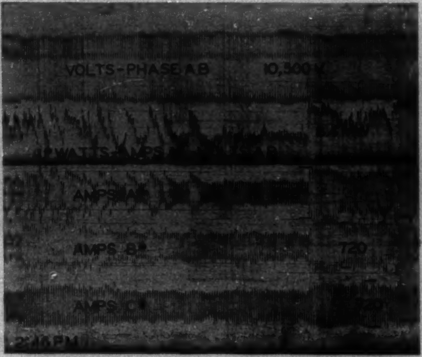
Large furnace swings probably caused by scrap falling against electrodes or falling into molten metal raising its level and short-circuiting the electrodes

Figure 11 (below). Oscillograph film taken during time of figure 10

The exact correlation is not known



problem. Voltage regulation was of course greater but not intolerable.

The maximum 15-minute kilowatt demand was 15,600 at approximately 75 per cent power factor or 20,800 kva.

The graphic charts show maximum amperes of 1,590 per phase in the 11-kv circuit. Due to the larger ammeter constant, overswinging did not seem to be as pronounced as in the initial furnace test.

The "Electrogear"—A New Electromechanical Vehicle Drive

ERNST WEBER
FELLOW AIEE

Synopsis: Within recent years a new electromechanical transmission known as the "Electrogear" has been developed for use in gas and Diesel engine cars of all types including busses, trucks, rail cars, and track-laying vehicles. The paper describes the principle of its operation which is basically a differential action between direct mechanical power transmission and a generator-motor system, interlinked by means of a permanently engaged planetary differential gear.

At the start, both the electrical and mechanical power flows are in the same direction, giving high torque multiplication. As the vehicle speed increases, the electrical power flow diminishes, goes through zero, and finally reverses its direction, leading to high speed, low torque operation with "overdrive." The torque ratio is thus continuously variable as in the gas-electric drive, and is controlled independent of road conditions by a small auxiliary generator which acts as the "brain" of the system. The design and installation of one specific Bus Electrogear is given in detail in order to illustrate the application to public transportation, though various other models have been built and demonstrated. Extensive test data graphically describe the superior performance of this new vehicle drive which combines the ideal flexibility and low maintenance cost of the gas-electric drive with the economy of the standard gearshift transmission. Actual operation requires only accelerator and brake, both acted on conventionally by means of the conventional pedals, and a selector switch with engine starting, forward and reverse positions. The engine speed varies continuously, and due to the fact that only a comparatively small part of the engine power is circulated through the electrical machines, the weight of the drive is about one-half of that of the gas-electric transmission. Since the Electrogear goes automatically and inherently into "overdrive" at higher car speeds on level road, and can be designed to keep the engine speed in its most economic range during the major part of full throttle acceleration, its fuel economy is at least as good as that of the standard gearshift transmission, and for heavy city schedules becomes even considerably better.

I. Introduction

EVER since internal combustion engines have been used for the propulsion of vehicles, attempts have been made in great number to overcome the fundamental problem of flexible transmission of torque from the gasoline or Diesel engine to the wheels.[1] Yet no practical solution has been found which merely by mechanical devices produces a continuously variable ratio between engine torque and driving torque and is controlled by the action of the driver of the vehicle.

One of the most unsatisfactory elements of the standard gearshift transmission is the mechanical clutch operated by a separate clutch pedal. Practical ways have been found now to replace this clutch by a hydrodynamic coupling or "fluid flywheel"[2,3] which essentially consists of two rotating vane systems; one connected to the driving shaft, acting as centrifugal pump, and frequently called the impeller; the other connected to the driven shaft, acting as a turbine, and frequently called the runner. Torque transmission is obtained by the fluid circulating through both sets of vanes whereby on account of friction losses a certain amount of slip occurs. Any change in impeller speed causes a corresponding but slightly lagging change in runner speed resulting in a smooth operation of the vehicle without jolts. Since this "fluid flywheel" only acts torque transmitting, it must be used in connection with torque multiplying gears, either manually operated as in Chrysler cars, or in connection with automatic gearshifts as in the "hydra-matic" drive of the Oldsmobile[4] or it can be combined with a semiautomatic transmission as the "Fluidgear" developed jointly by the A.C.F. Motors Company and the Spicer Manufacturing Company.[5]

A further step is the hydrodynamic transmission or "torque converter";[2,6] this device adds a stationary vane system to the hydrodynamic coupling as a reaction member changing the tangential velocity of the fluid and thus produces torque multiplication. As the vehicle starts, maximum torque multiplication is obtained with a slip of 100 per cent between impeller and runner, and as the vehicle speed increases, slip and torque multiplication decrease. At a predetermined speed of about 17 miles per hour, direct mechanical drive is established automatically, without action of the driver. Obviously, the efficiency and fuel economy in the hydrodynamic range of driving is considerably lower than in the standard gearshift transmission, though the acceleration can be made to be satisfactory.

In spite of this variety of more or less automatic transmissions now available,[7] none of these can truly lay claim to be the

Paper 41-28, recommended by the AIEE committee on land transportation, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted October 28, 1940; made available for preprinting December 4, 1940.

ERNST WEBER is research professor at the Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

Author's acknowledgments: Save for the enthusiastic and freely given co-operation of all the parties mentioned below, it would not have been possible to carry out successfully the very first design and construction of the Bus Electrogear. It is, therefore, a great pleasure to acknowledge the indebtedness to John Whitson of The Power Transmission Company of New York for providing the background, co-ordination and support, and arranging for the co-operation of all concerned; to Colonel H. W. Alden of The Timken-Detroit Axle Company, who was the first to recognize the possibilities of the Electrogear for use in busses and track-laying vehicles, and who initiated the project for designing and building the first units and assigned the design engineering to R. M. Herron, who also supervised the assembly and participated in the installation of the unit; to C. O. Guernsey of the J. G. Brill Company who furnished the bus and provided generous co-operation; to E. R. Martin of the Delco Products Division of General Motors Corporation, who was in charge of the construction of the electrical machines; to G. M. Stapleton of the Ward Leonard Electric Company for the design of the control equipment; to John H. Gethin of the Pittsburgh Testing Laboratory for faithful assistance in the installation and during the tests; to F. W. Kateley and J. F. Chapman of The J. G. Brill Company for their interest, help, and supervision during the tests in Philadelphia. This paper was prepared at the request of the committee on land transportation of which E. B. Fitzgerald of the American Car and Foundry Company is chairman. The writer is indebted to Mr. Fitzgerald for his many helpful suggestions, and to F. W. Kateley of The J. G. Brill Company and Earl E. Kearns of the General Electric Company for the comparative test data on the gearshift and gas-electric drives.

[1] For all numbered references, see list at end of paper.

ultimate solution of the fundamental problem of power transmission in individual vehicles as recently admitted by high authority in the automotive industry.[7a] The only and earliest solution outside the field of strictly mechanical means is the well-known gas-electric transmission in which the engine drives a generator at nearly constant speed and one or two motors are coupled to the driver axle. This gas-electric transmission has recently been considerably improved[8,9] and would appear to be the ideal solution since it gives a continuously variable torque ratio, were it not for the large loss of efficiency and the large size and weight of the electrical machines needed to carry the whole engine power.

The purpose of this paper is to describe the progress in the development of an entirely new principle of power transmission,[10] invented by A. H. Neuland[11] and developed during recent years through the support of The Power Transmission Company of New York City, owners of the patents. Fundamentally, it constitutes an electromechanical drive and is based upon a differential action between directly transmitted mechanical power and d-c electric power furnished by one electrical machine and consumed by another. The driving torque and therewith the torque ratio is controlled by conventional use of the accelerator pedal, and its variation is produced by a small auxiliary generator whose speed is proportional to vehicle speed. Since the transmission embodies electrical machines connected through the elements of a differential gear of the planetary type, the name "Electrogear" has been adopted for it.

The Electrogear has the extreme flexibility of the electric drive and, like this, gives a continuously variable torque ratio. In addition, it has the advantage of high fuel economy, since only a fraction of the mechanical power is transformed into electric power, and since the engine speed though variable can be kept within its most economic range even at the highest vehicle speeds, when overdrive automatically occurs. On account of the partial conversion into electric power, the sizes and weights of the electrical machines are considerably smaller than in the gas-electric drive with the attending advantages of lower currents and smaller commutators.

Designs of the Electrogear have been made and demonstration models built for several 5-passenger cars, for a 36-passenger city bus, and for a 12-ton track-laying vehicle. The Pittsburgh Testing Laboratory made extensive road tests of a five-passenger sedan with the Electrogear drive, and then duplicated the same tests of the same car with its conventional gearshift drive. The comparative results covered in a report[15] should be of interest to the automotive industry as well as to electrical engineers since they show that a transmission using electrical machines in proper combination with a differential gear can be just as efficient as a purely mechanical transmission.

The detail discussions in this paper however pertain to the bus application because the greatest variety of drives has been developed in this field, so that comparisons can readily be drawn from available commercial test and performance data.

II. Principles of Operation and Design

Figure 1 is a schematic sketch of the Electrogear drive with only the armatures of the electrical machines indicated for simplicity, figure 2 shows the connection diagram for forward operation of the vehicle, and figure 3 gives a more detailed sketch of the differential gear. The armature *BA* of the one electrical machine is directly coupled to the engine shaft *IS* and the ring gear *R* of the differential gear; this machine may, for convenience, be called booster. The armature *RA* of the second electrical machine is coupled to the sun gear *S* of the differential gear and usually is mounted on a hollow shaft or quill *Q;* this machine may, for convenience, be called reducer. Booster and reducer are series-wound d-c machines, both connected in series for forward operation of the vehicle as seen in figure 2. The auxiliary generator has its armature *REG* driven by suitable gears or by belt from the output shaft *OS*, which in turn carries the planet spider with the planets *P* of the differential gear. This auxiliary machine, called regulator for convenience, is connected parallel to the booster field; its function is the distinctive feature of the Electrogear.

1. OPERATION OF THE ELECTROGEAR

In forward operation, with the vehicle standing still and the engine idling, the ring gear and booster armature *BA* will turn with engine shaft speed, whereas the planet spider and output shaft are at rest. Thus, the sun gear with the reducer armature *RA* has to turn in a direction opposite to engine shaft rotation. Now, the electrical machines are so connected that under these mechanical conditions the reducer will act as self-excited generator and feed current into the booster, which will act as motor permitting just enough current flow to maintain polarities without moving the vehicle.

Depression of the accelerator pedal increases the engine speed and power and therefore the electric power generated by the reducer which drives the booster as motor in the same direction of rotation as the engine. Thus, the ring gear torque is actually the sum of engine and booster torques. Since both ring gear torque and reactive torque of reducer act in the same direction upon the planet spider, a considerable driving torque multiplication takes place comparable to "first gear" in mechanical transmissions; the planet spider starts revolving and the vehicle starts moving. As the vehicle, and with it the planet spider, speeds up, the reducer slows down so that without any further action the vehicle could reach only a comparatively low speed determined by the electromechanical balance of torques.

However, part of the main current is shunted through the regulator which has its field so connected as to generate a voltage in opposition to the voltage drop across the booster field. Since the regulator speed increases with vehicle speed, the regulator voltage also increases and eventually reverses the current in the booster field. The electrical design must, of course, correlate this period with the period in which the reducer has slowed down enough to be unable to drive the booster as motor, so that the regulator, furnishing from now on the field excitation of the booster in reversed direction, forces it to act as generator. With the main cur-

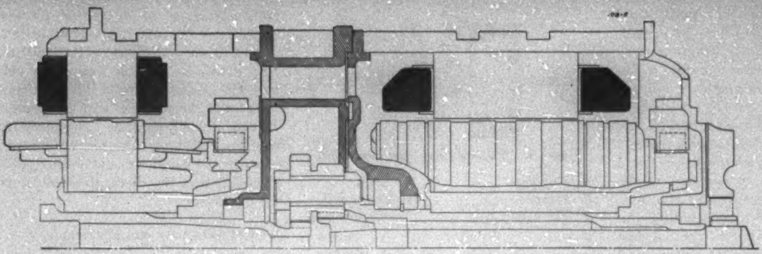

Figure 5. Simplified drawing of Electrogear layout for a city bus

rent continuing to flow in its original direction, the reducer must now reverse its direction of rotation to run as motor. It is quite obvious, at this point, that the regulator is the automatic governor of the booster and determines the over-all action of the electrical power flow which is differentially superimposed upon the mechanical power transfer. Since, in operation, the transitions from motor-to-generator state and vice versa are accomplished smoothly and without any interruption, the resulting variation in driving torque is also continuous and responsive to the degree of depression of the accelerator pedal which, in fact, is an inherent feature of this transmission.

As soon as the reducer reverses its direction of rotation, all three elements of the differential gear, namely ring gear, planet spider, and sun gear are rotating in the same direction. Obviously, at some particular vehicle speed the differential gear will rotate as a solid unit in which case the torque ratio between input and output must be unity, corresponding to "high gear" in the usual mechanical transmission. Advantageously, one can choose to have this occur well below top speed of the engine, preferably close to the most economic speed of the engine with respect to fuel consumption. Further increase of vehicle speed automatically brings about the condition of "overdrive," since the regulator output also increases and forces the booster to generate an increasing voltage at almost constant speed, which in turn speeds up the reducer as motor; thus the ratio of engine to vehicle speed decreases to a value below unity, which is determined primarily by the amount of conversion into electric power at top speed of the vehicle.

Reverse operation of the vehicle is obtained as in any electric drive by reversing the fields of both booster and reducer with the regulator disconnected from the booster field. The booster now acts as self-excited generator driven by the engine and the reducer runs as motor, speeding up in its idling direction of rotation which is opposite to engine shaft rotation. This forces the planet spider also to rotate in the direction opposite to that of the engine shaft which gives backward motion of the vehicle. The maximum reverse speed is of course limited by the electromechanical torque balance under these conditions but is sufficient for all practical purposes, since the maximum tractive effort in reverse operation is as high as 60 to 65 per cent of that in forward operation.

2. Special Features of the Design

The design of this electromechanical transmission requires a careful study of the interrelation of all component elements in order to obtain proper functioning and the economy in weight and cost which is all important for any vehicle drive. The choice of the rear axle ratio (for rear axle drive) and that of the ratio in the planetary differential are interdependent and are determined by the desired rate of initial acceleration and by the top speed of the vehicle. As mentioned above, the fuel economy can be influenced decisively by proper choice of the vehicle speed in full throttle acceleration at which "overdrive" sets in; in this respect particular attention has to be paid to the auxiliary generator or regulator. For best results, individual designs are desirable for different performance requirements, though within any particular class of vehicle a standard design can be used for the average requirements and adjustments made by the use of slightly different rear axle ratios as is customary with the standard mechanical transmissions.

The planetary differential gear of the ring gear type is most commonly used in vehicle drives. Referring to figure 3 and denoting with r the ratio of the number of ring gear teeth to the number of sun gear teeth one finds for the ratio G of the torques on output and input shafts the value

$$T_{OS}=\frac{r+1}{r}T_{IS}=GT_{IS} \tag{1}$$

Obviously, the largest value of G is obtained for the smallest value of r; for mechanical reasons, therefore, $G \leq 1.8$ which restricts this type of planetary differential to use in vehicles with low torque multiplication, as for example in passenger cars.

In order to obtain larger torque multiplication, a differential gear of the type shown in figure 4 and known as "reverted train" has to be used; on account of the two sets of planets it is often called double-planet gear. For reasons of con-

Figure 6. Photographic view of Electrogear on the dynamometer stand

struction the ratio of teeth in *B* to *A* is usually the same as that in *D* to *C*, and denoting it as *q*, one has for the torque ratio *G* of output to input shafts

$$T_{OS}=q^2T_{IS}=GT_{IS} \qquad (2)$$

This type of planet gear can, therefore, be used for any large torque multiplication within practical values, and has the further advantage that the quill *Q* carrying the reducer can be located either to the left or to the right of the planet gear. It has been applied in the bus drive and the drive for the track-laying vehicle.

The main electrical machines have to be designed with utmost economy in the use of materials. In a bus drive with a definite schedule the power requirements can easily be evaluated; the effective mean value of the losses with proper consideration of cooling conditions at the various vehicle speeds will lead to the customary one-hour rating as a basis for the design. In the case of vehicles for general service suitable assumptions must be made with respect to most frequent driving conditions and maximum possible overloads. In the designs built for the bus and track-laying vehicles glass insulation was used throughout to take full advantage of the maximum temperatures permitted by AIEE Standards for traction machines. Of course, only experience can tell what effective cooling the machines may have on account of their particular location on the moving vehicle. The test data below will illustrate these points more fully.

The most important element in the Electrogear transmission is the regulator since it determines and controls the operation of the booster as motor or as generator. Being connected in parallel to the booster field, it carries a large part of the main current in addition to the current which it produces by self-excitation. Furthermore, its magnetic characteristic must be such that at the highest vehicle speeds it will not, or only slightly, saturate in order to provide adequate excitation for the booster. Since it is a very low voltage machine, care has to be taken to obtain good commutation under all driving conditions. All these are requirements that can easily be satisfied by an adequate design, but they are quite different from those met with in the design of general purpose machines.

3. Example of Installation

As an illustration the Electrogear designed for an A.C.F. bus weighing 14,220 pounds empty and 19,420 pounds with seated load will be described. The basic data for the bus were furnished by the engineers of The J. G. Brill Company at Philadelphia. The bus was to be equipped with a Hall-Scott 135 engine mounted under the floor and delivering 116 brake horsepower at 2,000 rpm of which approximately 9 horsepower were used in accessories so that only 107 horsepower were available for the transmission. As a city bus the requirements were assumed to be 10 stops per mile, 11 seconds for each full stop, a scheduled speed of 11 miles per hour and acceleration up to 25 miles per hour between stops. The one-hour ratings of the electrical machines were—

Booster as motor
..........22.5 horsepower at 1,900 rpm
Reducer as generator
....................20 kw at 1,200 rpm

with maximum speeds of the booster about 2,600 rpm, of the reducer about 2,200 rpm; each had four main and four commutating poles, was series wound and designed for optimum voltage from the point of view of economy. Both main machines as well as the regulator were built and individually tested by the Delco Products Division of General Motors Corporation at Dayton, Ohio.

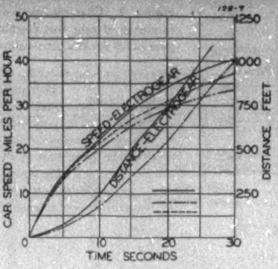

Figure 7. Full throttle acceleration of city bus

——————— Electrogear
— · — · — Gas-electric
- - - - - - - Gearshift

The mechanical layout was primarily determined by the available space between engine shaft flange and universal joint of the propeller shaft in the standard bus chassis. This put a limitation upon the axial extension of the armature end connections, but by placing the planet gear between booster and reducer and shortening the propeller shaft a solution was found satisfactory from all angles. The planet gear is of the double-planet type and uses the smallest feasible sun gear on the input side in order to utilize the space between the two main machines most economically. The complete layout, in simplified lines shown in figure 5, was made by The Timken-Detroit Axle Company, who also designed and built all mechanical parts and assembled the complete unit for installation. As seen, the assembly is extremely compact and utilizes the space within the bell housing, it provides excellent paths for the cooling air which is supplied through air cleaners, and it gives easy access to all brushes for examination and service. A photographic view of the assembly given in figure 6 shows the mounting on the dynamometer stand during preliminary tests. The mechanical construction also involves the brake drum as an integral part of the output shaft flange. Oil seals are incorporated in suitable form and number to insure proper local lubrication without permitting oil to enter into the electrical machines.

The actual weights (in pounds) of the various parts were as follows:

Booster (complete with shaft)	393
Reducer (complete with quill)	534
Regulator (complete with drive)	82
Planet gears	18
Electric control (complete without cover and brake resistor)	56
Air cleaners and miscellaneous parts	29
Total weight	1,112

Inasmuch as this was a sample unit and time was of essence, the material and dimension specifications of the design were not followed closely, so that the above actual weights of the booster and reducer exceeded the computed weights by about 150 pounds. Therefore the given weights do not in any sense constitute the most economic construction.

The electrical control[11] consists principally of a selector switch which connects the electrical machines for the three distinct operations: engine starting, forward, and reverse; and several relays which reduce the effort of the driver to a minimum, namely conventional operation of accelerator and brake pedals, and at the same time provide appropriate interlocks. The control equipment was designed with the co-operation of, and furnished by, the Ward Leonard Electric Company of Mount Vernon, New York.

The "starting" relay is operative only in the "engine starting" position of the selector switch and by interlock only when the accelerator pedal is depressed so as to avoid an accidental short circuit of the battery over the main circuit. Depression of the start button connects the conventional starting motor to the battery to start the engine and also sends current through the booster armature and the booster and reducer main fields in series, establishing the proper polarities for operation in either forward or reverse

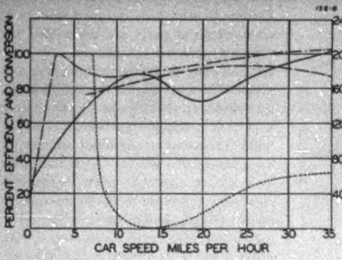

Figure 8. Characteristic performance of city bus Electrogear in full throttle acceleration

—·—·— Gas-electric engine speed
———— Electrogear engine speed
------- Electrogear conversion ratio (per cent of engine power)
— — — — Electrogear efficiency (driver to engine)

direction. This is entirely sufficient for all subsequent operations of the vehicle and no further teasing of the generator is required at any time.

With the selector switch in forward position, depression of the accelerator pedal operates the "accelerator" relay, which permits the reducer to build up self-excitation as generator and to accelerate the vehicle as previously described.

In order to provide the very desirable benefits of electrodynamic braking, the brake relay connects a brake resistor parallel to the two main armatures as soon as the brake pedal is slightly depressed, whereas full depression applies additionally the air brakes. Again, an interlock prevents simultaneous accelerating and braking by de-energizing the accelerator relay when the brake pedal is depressed.

As a protective feature a temperature-operated contact system is inserted close to the reducer main field. Should the temperature of the field coils exceed a critical value, these contacts open and prevent further operation of the accelerator relay and thus of the Electrogear until the electrical machines have cooled down sufficiently to avoid damage. Though this protector never had occasion to act even during the most severe test runs, there might be conditions of getting into deep ruts or similar difficulties when this feature would prove desirable.

III. Comparative Test Data on Bus Transmission

As mentioned above, the bus transmission was chosen as a representative illustration, because in commercial transportation fuel economy, low maintenance cost, durability, acceleration, gradability, ease of operation, and comfort of the driver are of particular importance. Consequently many attempts have been made to develop a bus transmission which would satisfactorily meet all these requirements. Thus, there are at present in actual use, in addition to the standard gearshift transmission, the torque converter[4] developed by the Spicer Manufacturing Company in collaboration with General Motors Corporation, the "Fluidgear" developed jointly by A.C.F. Motors Company and Spicer Manufacturing Company,[5] and the gas or Diesel-electric drives developed by the General Electric Company[8] and the Westinghouse Electric Manufacturing Company.[9] Both the torque converter and the Fluidgear have somewhat lower performance[13] than the standard gearshift transmission, the first with respect to fuel consumption, the second with respect to acceleration, so that comparison of the Electrogear performance will be made with the standard mechanical and the gas-electric drives.

In comparing Electrogear with gearshift performance it should be borne in mind that the test data available on the gearshift transmission are obtained with a skilled driver and constitute optimum results which are seldom attained in actual commercial service, whereas Electrogear as well as gas-electric test performance is reproducible uniformly with any driver, no skill being involved in the operation of these drives, as they require only conventional use of conventional accelerator and brake pedals.

For a fair comparison of these drives it is also necessary to take into consideration the differences in bus weight on account of the drive. It was agreed by the engineers consulted in the preparation of this paper that all test data should be compared on the basis of the following bus weights; with standard gearshift transmission 18,000 pounds; with Electrogear 18,500 pounds; with gas-electric drive 19,200 pounds.

1. Performance Tests With the Electrogear

During the summer of 1939 extensive tests were run with an A.C.F. bus equipped with the Electrogear transmission and a standard $6^1/_4$ ratio rear axle. In all tests the total weight of the bus was about 18,500 pounds. After preliminary tests had demonstrated the satisfactory over-all performance of the transmission and necessary adjustments had been made, final tests were run with calibrated measuring equipment. All the tests were carried on under the supervision of The J. G. Brill Company's (or A.C.F. Motors Company's) engineers and a representative of the Pittsburgh Testing Laboratory.

The acceleration runs were made on a concrete highway west of Philadelphia, and the average taken for several runs in each direction in order to even out possible differences in slight slopes. Speeds were measured by means of a "fifth wheel," mounted on the side of the bus and driving a Hasler-Tel integrating accelerometer, giving mean speed values for each second. The result is shown in figure 7 where speed and distance are plotted against time. According to the records the Electrogear accelerated to 40 miles per hour in 29.2 seconds, and to a distance of 1,000 feet in 26 seconds, which must be considered excellent for any bus of this size. As mentioned before, the Electrogear performance being inherently automatic it can always be reproduced by drivers without skill or familiarity with the principles of operation.

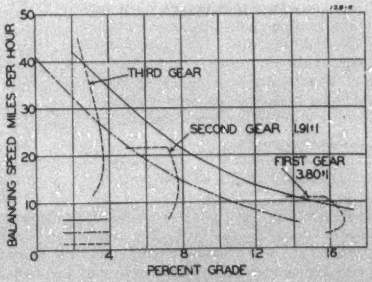

Figure 9. Gradability curves of city bus in terms of balancing speed against per cent grade

———— Electrogear
—·—·— Gas-electric
------- Gearshift

From readings of the currents and voltages during acceleration, the circulating electric power can be computed and compared with engine power. The conversion ratio plotted in figure 8 against car speed graphically shows the percentage of engine power which the Electrogear converts into electric power, and checks very well the theoretical values used in the design. It is quite obvious that during the major part of the acceleration period only a very small fraction of engine power is circulated electrically, so that the losses of the double conversion are very small. This is also expressed in the high values of efficiency, defined here as the ratio of power at the wheels to engine power and shown in figure 8. Finally, in the same figure, the engine speed during full throttle acceleration is also given; the moderate values up to 20 miles per hour vehicle speed, in spite of the high rate of acceleration, are indicative of low fuel consumption for heavy schedules.

In normal driving (at constant speed on level road) the above advantages are, of course, much more marked. Thus, in the present installation the "overdrive" becomes noticeable at about 35 miles per hour, i.e., the engine speed is held below the values which the direct drive of a mechanical transmission would require. Equally, the conversion ratio becomes lower than in acceleration, which improves the over-all efficiency particularly at the higher car speeds.

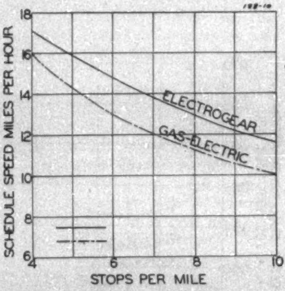

Figure 10. Schedule speed. Stops 11 seconds. Acceleration to about 25 miles per hour

— · — · — Gas-electric

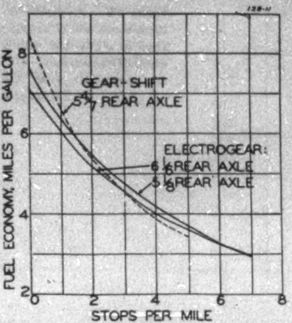

Figure 11. Fuel economy for various stops per mile and different rear axle ratios

——————— Electrogear (18,500 pounds)
- - - - - - - Gearshift (19,980 pounds)

Gradability tests were made on a special test hill near Philadelphia, which is about 700 feet long and has for the major part a grade of 15 per cent, tapering to about 12 per cent toward the top. From a standstill at the foot of the hill the bus was traveling at a speed of 10 miles per hour in less than 15 seconds, and was at the top of the hill at 14.5 miles per hour still accelerating. During this climb the engine speed was very low, with a maximum of 1,650 rpm at the top of the hill. Again, according to the records available to date, this performance was the best obtained on that hill with any bus transmission. On the basis of these and other tests, a gradability curve was computed giving the maximum speed of the bus attainable on various grades; the curve is shown in figure 9.

In order to check continuous performance and temperatures under severe strain the bus was operated for 3 miles with 13 stops per mile, and after a 5-minute interval for $7^1/_2$ miles with 10 stops per mile and 11 seconds per stop, and acceleration up to 25 miles per hour between stops. At the 114th stop the cooling water of the engine boiled over and the brakes were smoking hot. Yet the temperature of the Electrogear machines measured with thermocouples inserted in the field coils was 25 degrees centigrade for the reducer and 43 degrees centigrade for the booster lower than the permissible maximum temperature. The schedule speed during this breakdown test run, as checked repeatedly, was 11.6 miles per hour, taking 5 minutes 11 seconds for every 10 stops. On the basis of this as well as other tests, the schedule speed for various stops per mile was computed and is shown in figure 10. Gasoline consumption was also measured during the runs, giving 2.67 miles per gallon on this severe schedule.

For comparison with other drives, independent fuel consumption tests were carried on at length, for various stops per mile and acceleration up to 30 miles per hour. Figure 11 shows the results for two different rear axle ratios. It is most interesting to observe that the larger ratio $6^1/_8$ which was chosen in the design actually leads to higher fuel economy at heavier schedules than the $5^1/_8$ ratio, which in turn shows up slightly better up to 6 stops per mile. This justifies the selection of the $6^1/_8$ axle for the originally specified schedule of 10 stops per mile, and illustrates the flexibility of the Electrogear showing that it is easily possible to choose the most economical combination for every operating condition. An Electrogear design made for a schedule of 5 stops per mile shows a fuel economy of 8.5 miles per gallon at 30 miles per hour, and of about 4 miles per gallon at 5 stops per mile, which is considerably better than with the design for 10 stops per mile.

2. Comparison With Mechanical Gearshift Transmission

Through the courtesy of The J. G. Brill Company's engineers comparative test data were made available on the standard gearshift transmission in a bus of about the same seated weight and with the same size engine as used for the Electrogear. The ratios in the gearshift transmission were 3.80 for low gear, 1.91 for intermediate, and $5^4/_7$ for the rear axle. The acceleration curves were referred by adjustment of the acceleration rates to the comparative test weight of 18,000 pounds stipulated for the bus with the gearshift drive. The result is plotted in figure 7, demonstrating the superiority of the available continuous driving torque in the Electrogear as compared with the twice interrupted power flow in the gearshift transmission, which in spite of the almost equal initial acceleration rate causes a loss in momentum serious enough to affect the performance. This can be seen very much better in figure 12 in which the available instantaneous acceleration rates are plotted against car speed, and the vertical dotted lines represent the necessary interruptions in acceleration during the shifting of gears. Though the effect is pronounced in acceleration from a standstill, it is much more impressive when accelerating from a given car speed. Thus at 20 miles per hour the mechanical gearshift can produce only 0.76 mile per hour per second acceleration without shifting to second gear, whereas the Electrogear can deliver 1.52 miles per hour per second by mere normal use of the accelerator pedal.

The comparative gradability is plotted in figure 9 in terms of balancing speed, and demonstrates a further advantage of

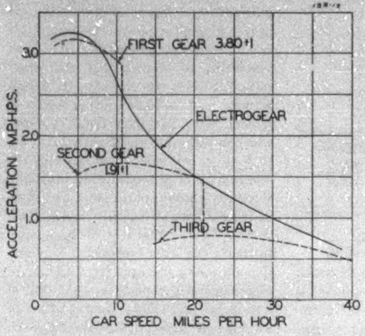

Figure 12. Available instantaneous rate of acceleration of a city bus with a gearshift transmission (----) as compared with the Electrogear

the Electrogear in hilly terrain where the loss of momentum during back shifting of gears is particularly annoying and traffic delaying. Thus, while the standard gearshift bus climbs a grade of only 3.5 per cent at 25 miles per hour, the same bus with an Electrogear will climb a 6.6 per cent grade at 25 miles per hour, which is important with respect to schedule speed on routes with grades. Obviously, this free availability and automatic adjustment of driving torque under all circumstances also indicates a considerable saving in fuel consumption for vehicles traveling in hilly country.

Though no curves are available to show the schedule speed of the gearshift bus directly, reference can be made to an available actual service comparison with the gas-electric drive,[14] which shows that at about the same acceleration rate the gearshift bus schedule is about six to eight per cent slower than that of the gas-electric bus. Since the Electrogear, as shown in figure 7, has better acceleration than the gearshift transmission, the difference in schedule speed in favor of the Electrogear bus would be even greater. At that, it should be kept in mind, in comparing the acceleration curves, that in the case of the gearshift transmission they are obtained with the best driver continuously using extreme care in shifting at the proper moment; such ideal conditions, however, cannot be continuously reproduced in actual service, so that actual schedule speed with gearshift transmissions (manual or automatic) must be lower than theoretically expected, whereas, as pointed out, the Electrogear performance is not dependent on driving skill for uniform efficiency.

In order to compare fuel consumption for various stops per mile and acceleration up to 30 miles per hour, figure 11 shows in dotted line latest data obtained by The J. G. Brill Company on a bus weighing 19,980 pounds and using the same type engine as the Electrogear bus. Since fuel consumption is not proportional to bus weight, reference cannot easily be made to the comparative weight of 18,000 pounds; however, it is quite apparent that the repeated shifting of gears decreases relatively the fuel economy at the heavier schedules, bringing it into the range and below that of the Electrogear beyond about five stops per mile. The influence of shifting gears can best be seen in figure 14 in which the specific fuel consumption for full throttle acceleration is plotted against bus speed, based upon a typical fuel consumption curve of the Hall-Scott 135 engine shown in figure 13 and the engine speed variation shown in figure 8 for the Electrogear, and computed from the gear ratios for the gearshift bus. Over the entire range from 5 to 26 miles per hour (the speed most frequently used in city service) the Electrogear designed for heavy city service keeps the engine in the range of lowest possible fuel consumption. Flexibility of the Electrogear design makes equal or better fuel economy available in busses with lighter city service or for intercity use. In general, then, the Electrogear proves to be at least as efficient as the gearshift drive, and for any particular operating requirements can be made more economical. This clearly shows that the low efficiency of electric drives disappears when the electrical machines are used in proper combination with mechanical elements.

3. Comparison With the Gas-Electric Drive

Through the courtesy of the General Electric Company the performance data of a gas-electric transmission using the same Hall-Scott 135 engine as the Electrogear and the standard gearshift transmission were made available, so that a direct comparison is possible. On account of the greater weight of the gas-electric drive the test weight of the bus in this case was 19,200 pounds. The shunt-wound generator is of the type *GT* 1501 and has a net engine power of 107 horsepower at 2,000 rpm; the series-wound motor is of the type *GE* 1205; the rear axle ratio is $6^1/_8$, comparing with $6^1/_6$ for the Electrogear.

The speed-time curve of figure 7 indicates that the gas-electric acceleration is considerably less than that of the Electrogear, especially at car speeds beyond about eight miles per hour. This is easily accounted for by the fact that for city bus installation the Electrogear is designed to have very little engine power circulating through its electrical machines between 8 and 24 miles per hour car speed, as seen from figure 8, so that there is hardly any conversion loss in that range of car speed. On the other hand in the gas-electric drive the electrical machines continuously carry all the available power so that a considerable conversion loss is sustained. The same explanation holds, of course, for the divergence of the distance-time curves, also shown in figure 7.

For the same reason, the gradability of the Electrogear is considerably higher than that of the gas-electric drive using the same engine, as seen in figure 9, where the balancing speeds are plotted against per cent grades. However, these curves also illustrate particularly well the singular advantage of a continuously variable torque ratio; namely, to permit considerably higher speeds on grades on which the mechanical drive must shift gears and thus lose momentum. Thus at 15 miles per hour car speed the bus with mechanical transmission can climb only a 3.5 per

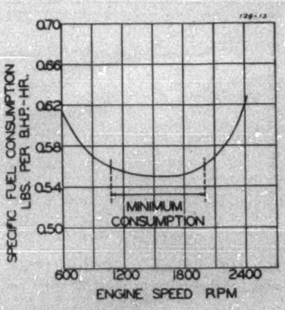

Figure 13. Specific fuel consumption of Hall-Scott 135 engine for full throttle setting

cent grade, the gas-electric bus about a 7.7 per cent grade, and the Electrogear bus even an 11 per cent grade as demonstrated in tests.

Figure 10 shows that the schedule speed of the gas-electric drive is about 1.6 miles per hour lower than that of the Electrogear, assuming 11-second stops in each case. Obviously this difference is due to the considerable difference in acceleration rates already pointed out in connection with figure 7.

Comparison of the fuel consumption per engine horsepower-hour is plotted in figure 14 on the basis of the full throttle specific fuel consumption of the engine given in figure 13 and of the engine speed curves for the various drives. For the gearshift the engine speeds are computed according to the gear ratios with the assumption that shifting is done when the engine speed reaches 2,000 rpm. For the gas-electric drive the engine speed variation was supplied with the performance data as plotted in figure 8 for comparison with the actual engine speed in Electrogear performance. Figure 14 shows the fuel consumption per engine horsepower-hour in full throttle acceleration to be as follows: highest with the gearshift drive (due to the fact that the engine goes through its entire speed range for each gear ratio); up to 12 miles per hour the same with the Electrogear as with the gas-electric drive; lowest with the Electrogear above 12 miles per hour; since the Electrogear uses much less engine power under all conditions it is evident that its total fuel consumption in full throttle acceleration must be the lowest.

Though no curves are available which would permit a direct comparison of the total fuel economy in commercial service of the gas-electric drive with that of the Electrogear, one can judge from comparisons of the gas-electric drive with the equivalent gearshift transmissions obtained in actual operation[14] that the average fuel consumption of the gas-electric drive is about 20 per cent higher if the acceleration is about the same in both cases. The gas-electric total fuel consumption should be even higher in comparison with the Electrogear since it has been established by tests that in a schedule of five stops per mile or more the Electrogear city bus is even more economical than the gearshift bus.

IV. Summary

The five principal requirements of an ideal power transmission from the gasoline (or Diesel) engine to the driver axle of a vehicle can be formulated as: first, a continuously variable torque ratio; second, effective loading of the engine under all driving conditions; third, uniformly economic operation at all vehicle speeds; fourth, driving ease; fifth, durability and low maintenance.

The Electrogear has demonstrated that it satisfies all of the above requirements to a higher degree than any known mechanical, hydraulic, or electrical transmission. There is no loss of momentum as in shifting gears, and the engine is never disconnected. Effective engine loading and "overdrive" are inherent features, fully automatic without any facilitating device. The all-around performance of the Electrogear as demonstrated by the Philadelphia tests is superior to that of other known transmissions, and it is significant that the best performance is always automatically produced without calling for skill or judgment. The driver has only the conventional accelerator and brake pedals to use in a conventional way, he has nothing to think about and no controls to manipulate. The durability and low maintenance cost of electrical machines are sufficiently well established by the gas-electric drives still in operation with 400,000 miles or more to their credit. Auxiliary electrodynamic braking (to reduce brake maintenance cost), particularly valuable in busses with heavy city schedules, can easily be made available with the Electrogear.

The design of the Electrogear is simple and flexible, permitting adaptation to any type vehicle. In large vehicles using conventional gas-electric or automatic multishift drives the Electrogear saves space, weight, fuel, and possibly initial cost. Its comparatively low weight opens a wide field of application in medium and light-weight vehicles in which automatically variable infinite ratio transmissions are desirable. To be simple, such transmissions must be electrical.[7a] It is not possible to simulate even by complicated mechanical devices all the desired transmission characteristics which are normally inherent in electric drives. Attempts by mechanical engineers to do so have resulted in increasing the weight and cost of mechanical transmissions to an extent approaching the Electrogear in large production.

Factors Influencing the Mechanical Strength of Cellulose Insulation

F. M. CLARK
ASSOCIATE AIEE

CELLULOSE insulation, like mineral oil with which it is usually associated in high-voltage electrical apparatus, is subject to deterioration in an increasing degree as the temperature of exposure is raised. This deterioration is a manifestation of the chemical instability of the cellulose. For a proper understanding of this change, it must be recognized that the fundamental chemical reactions involved are of two types. There are those changes which result from the oxidation of the cellulose and those which arise from the decomposition of its molecule. These changes are invariably intermingled in the normal commercial use of cellulose dielectric materials. To prevent dangerous deterioration and to secure the maximum service life of cellulose insulation, the effect produced by each type of reaction, the probability of its occurrence, and the means for its control must be carefully evaluated.

In a previous article[1] the author has described the mechanical and electrical changes in cellulose promoted by thermal decomposition in contrast to oxidation effects. It has been shown that cellulose will change mechanically and electrically with accompanying increase in color and acidity when heated at temperatures even as low as approximately 130 degrees centigrade under conditions which exclude the possibility of oxidation. These changes have been attributed to a molecular decomposition of the cellulose which culminates in the active evolution of gases, water, and other volatile products at temperatures above 130 degrees centigrade.

One of the objects of the present paper is to evaluate from the standpoint of mechanical strength those deteriorating changes in cellulose insulation which are caused by oxidation in contrast to those which result from the purely thermal decomposition of the cellulose molecule. Linen capacitor paper and Manila paper are used to illustrate the test results. These papers are selected because of their industrial importance. Other cellulose insulations, as for example kraft paper, have been found to be of similar behavior. The tensile strength of the insulation has been accepted as a gauge of its mechanical properties.

The Dormant Period

Cellulose insulation when heated actively exhibits evidence of molecular decomposition only after a "dormant" period, the length of which depends on the conditions of the heat treatment. Foremost among the conditions of importance are the temperature applied, the accumulated thermal history of the cellulose, and the presence or absence of an impregnating liquid such as mineral oil. In general, for unimpregnated insulation, gas evolution and other evidence of serious decomposition are observed after about 12 hours of heating at temperatures higher than 130 degrees centigrade. With oil-treated cellulose insulation, the effect of temperature has been more carefully delineated. Figure 1 illustrates for oil-immersed linen paper the length of the "dormant" period within which no gas is evolved at temperatures from 145 degrees centigrade to 200 degrees centigrade.

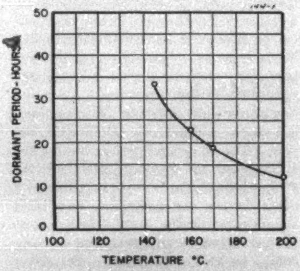

Figure 1. The "dormant" period is the duration of heat treatment which can be applied to cellulose insulation in the absence of oxidation without evolution of gases indicating molecular decomposition

The insulation used is vacuum-dried, oil-impregnated, and oil-immersed linen paper

It is obvious that the single effect of oxidation in promoting cellulose deterioration becomes of major importance only when the effects of molecular decomposition are avoided. It is within this range that the use of an inert gaseous atmosphere such as nitrogen can be expected to have its greatest stabilizing effect. When exposed to more severe conditions of temperature and time so that the "dormant" period is exceeded, molecular decomposition may become the dominant deteriorating factor. Adverse results are produced both directly as a result of pyrochemical change and indirectly because of the corrosive character of the decomposition products formed. It is during this period that the beneficial effects of a nonoxidizing atmosphere such as nitrogen gas are of decreasing, and frequently of negligible, importance.

Conditions Which Affect Aging

When cellulose insulation is exposed to temperatures of normal dielectric use, the rate of deterioration in tensile strength is dependent on the conditions of the heat treatment. Important factors are the temperature applied, the length of the exposure, and the presence or absence of an oxidizing atmosphere. The close intermingling of these factors and the great importance of the first two in producing radical changes in the tensile strength of the cellulose insulation have served to confuse their proper evaluation

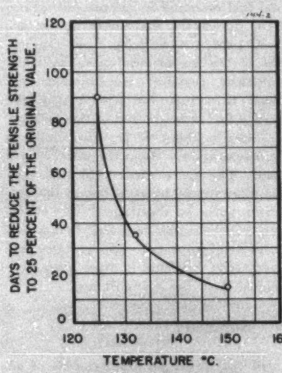

Figure 2. Dry Manila paper will deteriorate mechanically when heated in sealed tubes in contact with nitrogen gas

---

Paper 41-44, recommended by the AIEE standards committee, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted October 25, 1940; made available for preprinting December 11, 1940.

F. M. Clark is technical assistant for the General Electric Company, Pittsfield, Mass.

[1] For all numbered references, see list at end of paper.

to the extent that oxidation is frequently looked upon as the fundamental cause of all of the deterioration observed. This is not true, for cellulose insulation will deteriorate even in the complete absence of any oxidizing gas or other source of oxygen. This is illustrated in the data of figure 2. In this series of tests, Manila paper, vacuum dried but not oil impregnated, has been heated in sealed bombs at temperatures from 125 degrees centigrade to 150 degrees centigrade under 250 pounds of dry nitrogen gas. The results are expressed in terms of that period of time necessary to reduce the tensile strength to 25 per cent of the original value. The rapid loss in tensile strength with the increasing temperature of the exposure in nitrogen gives warning against too great an emphasis of the oxidation factor as the fundamental cause of cellulose deterioration.

The Stable Period

Available data indicate that, even under the most severe deteriorating conditions, there is an initial period during which the cellulose insulation suffers no loss in tensile strength. During this interval it may even exhibit slight increases. This period has been termed the "stable period." It corresponds to but is not of as great a duration as the "dormant" period discussed in a previous paragraph. After passing through the "stable period" chemical reactions are initiated which affect the mechanical strength of the insulation and which at temperatures above 130 degrees centigrade culminate in the evolution of gases, water, and other volatile products.

The duration of the "stable period" decreases sharply with increased temperature above 100 degrees centigrade. The period of stability is clearly evident in the tests of figures 10 and 11 which describe the behavior of vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper. The "stable period" for each of the relations of figures 10 and 11 is reproduced for purpose of clarity in figures 3 and 4.

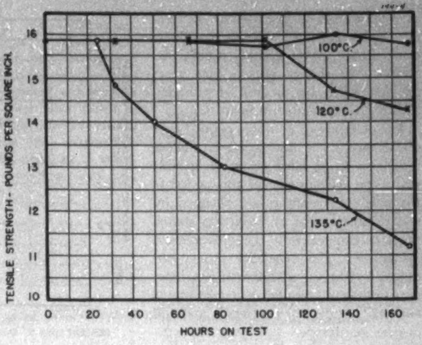

Figure 4. Showing the "stable period" of vacuum-dried, mineral-transformer-oil-treated, and oil-immersed 0.003-inch Manila paper when heated in contact with nitrogen gas

The length of the "stable period" is affected by the presence of an oxidizing atmosphere. This is demonstrated in the following data taken from figures 3 and 4.

Test Temperature (Degrees Centigrade)	Length of "Stable Period" in Hours		Per Cent Decrease in Duration of Stable Period Due to Oxidation
	For Run in Oxygen Gas	For Run in Nitrogen Gas	
100	101	168	40
120	33	101	68
135	16	24	33

The effect of oxidation on the duration of the "stable period" of oil-treated and oil-immersed Manila paper decreases as the temperature is lowered. As illustrated in figure 5, at temperatures as low as 85 degrees centigrade, the accelerating effect of oxidation can be expected to disappear. Tests at temperatures in the range of 85 degrees centigrade are of long duration and subject to wide variation, but in general, have served to substantiate this expectation.

When the cellulose is exposed to higher temperatures, the effect of oxidation on the length of the "stable period" does not increase indefinitely. This results because of the increasing importance of the second major factor, molecular decomposition which also greatly affects the rate of cellulose deterioration. The advantageous effect of the presence of nitrogen gas in prolonging the "stable period" of oil-treated cellulose reaches its maximum value at approximately 120 degrees centigrade. With higher temperatures of aging, the pyrochemical decomposition of

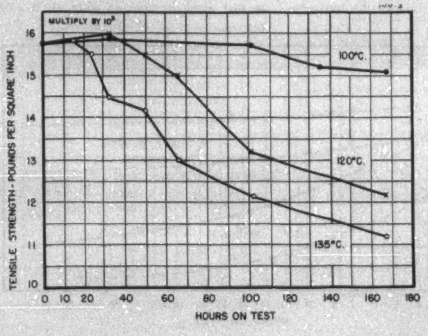

Figure 3. Showing the "stable period" of vacuum-dried, mineral-transformer-oil-treated, and oil-immersed 0.003-inch Manila paper when heated in contact with oxygen gas

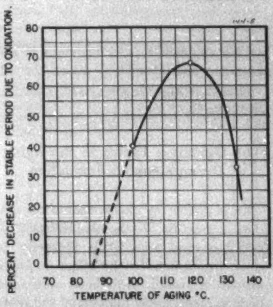

Figure 5. The effect of oxidation on the duration of the "stable period" for vacuum-dried oil-impregnated, and oil-immersed 0.003-inch Manila paper reaches its maximum at approximately 120 degrees centigrade

the oil-treated cellulose assumes increasing importance. As a result, the duration of the "stable period" rapidly decreases even though all oxidizing gases are eliminated by the use of nitrogen. This is also illustrated in figure 5.

The existence of a "stable period" is of importance in the application of cellulose insulation in oil-filled electrical apparatus. The prolongation of this period is the most important result obtained by the elimination of an oxidizing atmosphere in contact with the oil-immersed insulation. The beneficial results obtained by the use of nitrogen gas, however, are largely limited to temperatures between 100 degrees centigrade and 120 degrees centigrade. For lower temperatures, the oxidation effect is of negligible importance. For higher temperatures, the pyrochemical decomposition reaction of the cellulose rapidly increases in importance and ultimately masks the advantages normally associated with the use of nitrogen gas.

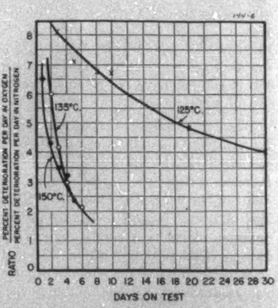

Figure 6. In the heat treatment of vacuum-dried but unimpregnated 0.003-inch Manila paper in sealed bombs under 250 pounds gas pressure, the deterioration in tensile strength is accelerated by the presence of oxygen

The Oxidation Factor in the Aging of Unimpregnated Insulation

In studying the importance of the oxidation reaction in the deterioration of cellulose insulations, it is necessary to differentiate between its effect on those insulations which have been oil-treated and are tested under mineral oil and those insulations which are tested without oil impregnation and in direct contact with an oxidizing atmosphere. In order to illustrate more clearly the effects of oxidation in terms of tensile strength, it has been found desirable to exaggerate the oxidation reaction by the use of oxygen gas in place of air. The effect on unimpregnated insulation is easily demonstrated. Figure 6 illustrates the importance of oxidation as a factor in the mechanical deterioration of dried but unimpregnated 0.003-inch Manila cable paper, aged at 125 degrees, 135 degrees, and 150 degrees centigrade in sealed bombs under 250 pounds of gas pressure. The results are expressed in terms of the accelerated rate of deterioration produced by the presence of oxygen gas as compared to similar aging in the presence of nitrogen. As the deterioration of the cellulose progresses, irrespective of the temperature of test, the accelerating effect of oxygen gas rapidly diminishes. During the initial state of the temperature exposure, however, the increased rate of aging due to the oxidation of the unimpregnated insulation reaches a high value.

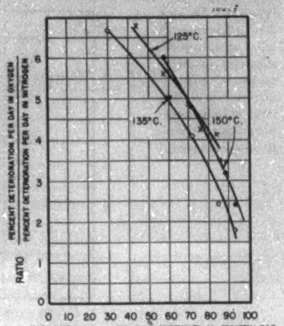

Figure 7. When vacuum-dried but unimpregnated 0.003-inch Manila paper is heated in sealed bombs under 250 pounds of gas pressure, the loss in tensile strength is accelerated by the presence of oxygen gas to approximately the same extent as the temperature is changed within the range from 125 degrees centigrade to 150 degrees centigrade

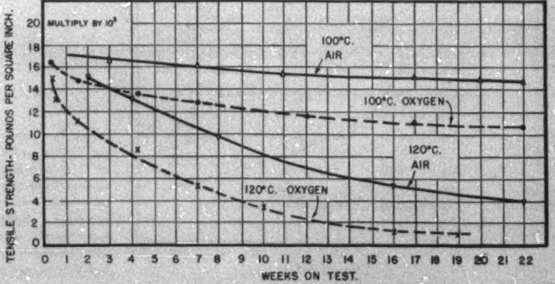
The marked effect of the oxidation reaction during the initial stages of the high-temperature exposure of dried but unimpregnated cellulose results from the longer duration of the "stable period" when the insulation is in contact with a nonoxidizing atmosphere. When once the "stable period" in nitrogen gas has been passed, however, and the paper begins to deteriorate because of pyrochemical decomposition, the increased rate of deterioration in oxygen gas as compared to that observed in nitrogen rapidly decreases. The decrease is substantially independent of the temperature. This is illustrated in the data of figure 7 which correlate the accelerating effect of oxidation caused by the presence of oxygen gas with the degree of deterioration observed. It is important to note that with dried but unimpregnated Manila paper, even though the effect of oxidation decreases as the deterioration progresses, there is nevertheless a pronounced acceleration of deterioration throughout the whole mechanical life of the insulation.

The Oxidation Factor in the Aging of Oil-Impregnated Insulation

In order to evaluate the importance of oxidation in the deterioration of oil-treated and oil-immersed cellulose insulation, it has been found desirable, as in the study of the unimpregnated insulation, to exaggerate those factors which accelerate oxidation. For this purpose, pure

Figure 8. When vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper is aged in glass tubes sealed at atmospheric pressure, the presence of oxygen gas accelerates the loss in mechanical strength as compared to that which is obtained when air is used



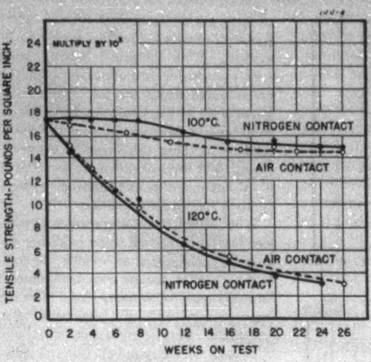


Figure 9. The loss of the tensile strength for vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper when aged in contact with nitrogen gas in glass tubes sealed at atmospheric pressure closely duplicates the deterioration observed when air is substituted for the nitrogen

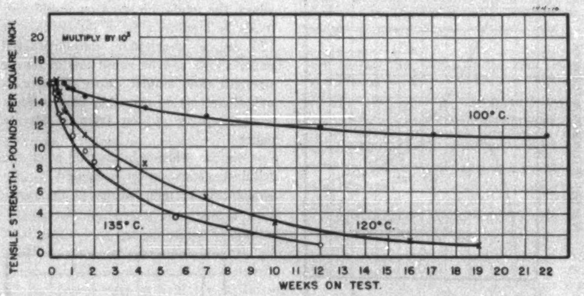

Figure 10. The loss in mechanical strength of vacuum-dried, oil-impregnated, and oil-immersed 0.003-inch Manila paper when heated in sealed tubes in contact with oxygen gas

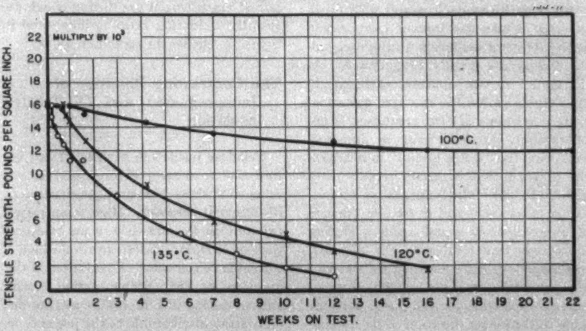
oxygen has been used in place of air. The oxygen gas has been applied both at atmospheric pressure and at 250 pounds per square inch in sealed bombs. Temperatures of test as high as 200 degrees centigrade have been investigated.

The results of accelerated tests in which the possibility of oxidation has been greatly exaggerated must be considered merely as the ultimate limit of oxidation. It must not be concluded from such tests that an equal degree of deterioration will be obtained for the same oil-treated and oil-immersed insulation in contact with the air which is normally present in commercial usage. A typical comparison of the aging of 0.003-inch Manila paper in air and in oxygen is illustrated in figure 8 for tests at 100 degrees and 120 degrees centigrade. The deterioration observed in the insulation aged in contact with air in figure 8 is substantially the same as that observed when the insulation is aged in contact with nitrogen under similar test conditions (figure 9).

Despite the difference in the rate of aging in oxygen and in air, the use of oxygen serves the practical laboratory purpose of bringing out the effects of oxidation under the most favorable, lower temperature conditions at which the effect of nonoxidizing chemical changes are reduced or eliminated. Figures 10 and 11 give detailed illustrations of the aging of 0.003-inch vacuum oil-treated and oil-immersed Manila cable paper sealed in glass tubes at atmospheric pressure, the surface of the oil being in contact with oxygen and with nitrogen gas.

One of the outstanding characteristics which distinguishes the aging of cellulose insulations in contact with oxygen gas from similar aging in contact with nitrogen is the shorter duration of the "stable period" when oxidation occurs. It is obvious from the data presented that any evaluation of the possible acceleration of aging due to oxidation will depend upon that stage of the heat treatment selected for the comparison. If an interval during the "stable period" is selected as the time of comparison, it will be concluded that oxidation is of serious import. If on the other hand, the point of comparison is taken after considerable mechanical deterioration has occurred, entirely different conclusions will be drawn. This is illustrated in figure 12, based on the data of figures 10 and 11. The acceleration of mechanical deterioration due to the presence of oxygen as compared to nitrogen gas is shown as a function of the duration of the aging exposure at 100 degrees centigrade, 120 degrees centigrade, and 135 degrees centigrade. At the lower temperature pronounced oxidation effects are observed during the initial stages of the test. At the end of about four days of aging, the deterioration in oxygen gas at 120 degrees centigrade is approximately $4^1/_2$ times faster than in nitrogen. This results from the longer duration of the "stable period" in the absence of oxi-

Figure 11. The loss in mechanical strength of vacuum-dried, oil-impregnated, and oil-immersed 0.003-inch Manila paper when heated in sealed tubes in contact with nitrogen gas



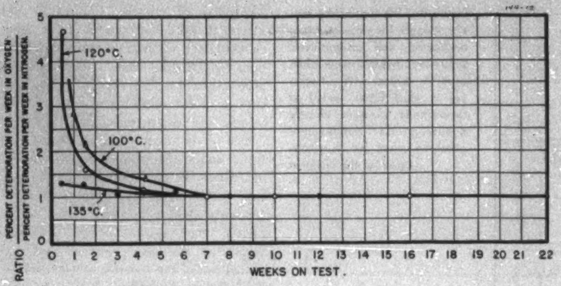


Figure 12. When vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper is heated in glass tubes sealed at atmospheric pressure, the oxidation factor assumes decreasing importance as the aging run progresses

dation effects. At the end of this "stable period" however, rapid changes in the oxidation ratio occur. Deterioration of the insulation in contact with nitrogen gas causes the oxidation ratio to fall rapidly. Within the limits of the available data, it is concluded that the rate of deterioration of the cellulose is progressively less affected by oxidation as the aging continues. When the deterioration has progressed to the extent that approximately 50 per cent of the original strength has been lost, the effects of the oxidation reaction are masked by the increasing importance of pyrochemical deterioration.

A further illustration showing the change from a condition of oxidation type of deterioration to a condition where the pyrochemical type predominates is illustrated in figure 13. In this study the dried, oil-impregnated, and oil-immersed 0.003-inch Manila paper insulation is heat treated at 200 degrees centigrade in contact with oxygen gas and with nitrogen gas. Under this type of deterioration both factors of oxidation and pyrochemical change are greatly exaggerated. As illustrated in the analysis of figure 13 the "stable period" in nitrogen gas under these conditions of heat treatment is approximately one-half hour in duration. Following the "stable period" in nitrogen, the deterioration increases rapidly to a maximum, after which the rate of deterioration in nitrogen and in oxygen appears of approximately equal value. During subsequent heat treatment, the only distinguishable feature between the deterioration resulting from the aging in nitrogen gas as compared to oxygen gas is attributable to the longer duration of the "stable period" in nitrogen gas during which period the oxidation ratio as illustrated in figure 14 reaches its maximum value.

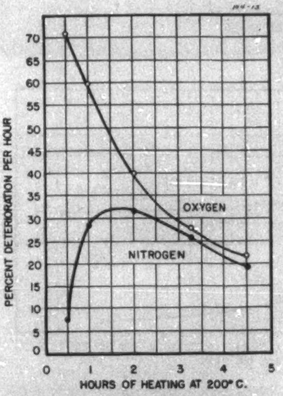

Figure 13. When vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper is aged at 200 degrees centigrade in glass tubes sealed at atmospheric pressure, the effects of oxidation, clearly evident in the initial stages of the heat treatment with oxygen are later masked by the presence of pyrochemical deterioration which occurs even in the presence of nitrogen gas

The Contrasting Behavior of Unimpregnated and Oil-Treated Insulation

Cellulose insulation whether tested before or after mineral oil impregnation and immersion shows the same peculiarities in its chemical behavior. High-temperature exposure in the presence of an oxidizing gas causes an initial deterioration which is traceable to the effect of oxidation on the duration of the "stable period." Examined during this interval, a marked deterioration attributable to the presence of oxygen gas as compared to the corresponding change in nitrogen gas is clearly evident. With continued heating, however, pyrochemical decomposition changes are initiated which become of increasing importance as the insulation is subjected to exhaustive treatment. It is the interrelation of these two types of chemical change and their modification as a result of oil impregnation and immersion which compels special consideration.

When dried but unimpregnated cellulose insulation is aged in an oxidizing atmosphere, the fibers are in intimate contact with what may be considered an unlimited supply of oxygen. Aged after oil impregnation and oil immersion, the amount of immediately available oxygen is limited to that supplied from oil solution. The result is that at temperatures where the oxidation reaction would normally be predominant, as for example at 120 degrees centigrade, unimpregnated paper shows a more rapid loss in tensile strength than similar paper oil impregnated and oil immersed. This is illustrated in figure 15 for tests on Manila paper.

A similar relation holds true when the cellulose deterioration is caused by the application of temperature in the range

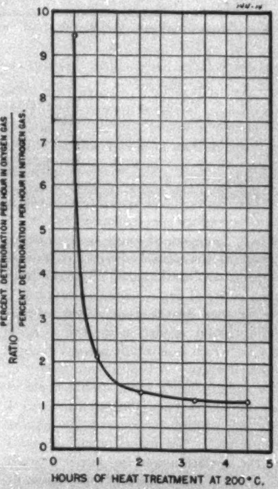

Figure 14. Showing the marked decrease in the oxidation factor after the end of the "stable period" for the aging of vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila paper in sealed glass tubes at 200 degrees centigrade

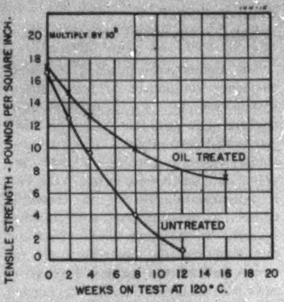

Figure 15. The mechanical aging of vacuum-dried 0.003-inch Manila paper is decreased as the result of impregnation and immersion in mineral transformer oil

The heat treatment in this illustration is carried out in glass tubes sealed at atmospheric pressure, the gas present being dried air

where pyrochemical decomposition is rapid and severe even in the presence of nitrogen. This is not unexpected in view of the fact that, as already described in a previous paragraph, the "dormant" period is increased as a result of oil impregnation and immersion. The longer duration of the dormant period for oil-treated and oil-immersed insulation in the absence of oxidation is undoubtedly related to the slower rate of acid formation in paper when exposed to high temperatures after oil treatment.[1] The result is that at a temperature of 135 degrees centigrade, dried but unimpregnated Manila paper deteriorates in tensile strength at a more rapid rate than does similar paper after oil impregnation and oil immersion. This is illustrated in figure 16.

In comparing the stability of cellulose insulation before and after oil impregnation the conditions of the comparison must be carefully stated. Dried but unimpregnated cellulose may be expected to deteriorate more rapidly than the same material after oil impregnation when the conditions of the temperature treatment are such that severe oxidation or pyrochemical reactions are possible. Heated under conditions such that oxidation and pyrochemical changes are of minor importance, the mechanical deterioration of the cellulose insulation is substantially unaffected by the presence of the impregnating mineral oil in which the material may be immersed.

Summary

1. Cellulose insulation will deteriorate in mechanical strength at a rate which increases with the increasing temperature of exposure. Deterioration will occur in the absence of an oxidizing atmosphere.

2. The rate of cellulose deterioration at a fixed temperature varies as the heat treatment is continued.

3. The mechanical deterioration of cellulose insulation at elevated temperature is the result of oxidation and pyrochemical decomposition.

4. When heated, cellulose passes through a "stable period" during which the mechanical properties are maintained. The presence of oxygen is chiefly effective in reducing the duration of this "stable period."

5. The single effect of oxidation is restricted to the initial periods of treatment at temperatures lower than approximately 120 degrees centigrade. At higher temperatures, pyrochemical decomposition occurs. Even in the most favored temperature range, the effect of cellulose oxidation merges into the effects produced by pyrochemical decomposition as the deterioration progresses.

6. Heated under conditions which favor oxidation or pyrochemical change, the unimpregnated cellulose insulation deteriorates more rapidly than the same insulation after oil treatment and immersion.

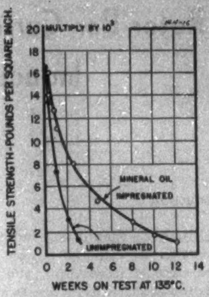

Figure 16. When heated at 135 degrees centigrade in sealed glass containers in contact with nitrogen gas, the rate of loss in tensile strength of dried 0.003-inch Manila paper is substantially decreased as a result of impregnation and immersion in mineral transformer oil

7. The effect of oxidation is accelerated when pure oxygen gas is in contact with the insulation. No substantial difference in the rate of mechanical deterioration is observed when the oil-treated and oil-immersed insulation is aged in contact with nitrogen gas as compared to aging in contact with air.

Rotor-Bar Currents in Squirrel-Cage Induction Motors

J. S. GAULT
MEMBER AIEE

Introduction

THE rotor of a squirrel-cage induction motor is an extremely simple and rugged piece of mechanism; and due largely to this simplicity, it resists accurate analysis of its behavior by ordinary testing technique. Its design has been perfected by cut and try methods, making assumptions with respect to rotor current to simplify the theory; but the actual current in the bars has remained a mystery. The purposes of this paper are: first, to present oscillograms of rotor-bar currents; second, to extend the theory of induction motors to include the computation of rotor-bar currents; and third, to show the effect of the rotor current harmonics upon the efficiency of the motor.

Rotor-Bar Currents

The current in the rotor bars of a squirrel-cage induction motor is a composite wave of complicated form in which, however, three main components are prominent. In addition to the slip-frequency component which increases directly with load, there is a component due to nonuniform reluctance, the tooth-frequency component. The magnitude of this component depends primarily upon flux density but also increases with load; its frequency depends upon the number of stator teeth and the speed. The tooth-frequency component is very pronounced in a machine with open slots and is considerably reduced by using closed slots or nearly closed slots. The third main component of rotor frequency is caused by the nonsinusoidal distribution of stator current, and will be designated the band-frequency component.

A polyphase stator winding excited by current of sinusoidal wave shape gives a stator magnetomotive force with nonsinusoidal distribution. This would produce a rotating field with nonsinusoidal shape, although the flux density at every point along the air gap would vary sinusoidally in time to give a sinusoidal generated voltage in the stator. In a wound-rotor motor, space harmonics in the stator flux wave produce corresponding harmonics in the rotor generated voltage; but in a squirrel-cage motor, irregularities in the flux wave are practically eliminated by currents induced in the short-circuited rotor conductors. The rotor current distribution is such that the total current distribution, rotor plus stator, is sinusoidal. This hypothesis is given in Professor Bailey's book,[1] and is substantiated by analysis of the rotor current oscillograms included in this paper.

Computation of Band-Frequency Component

The method of computing the band-frequency component of rotor current will be shown by a specific example, using a three-phase winding with two-thirds pitch, 12 slots per pole. The curves of stator current distribution over two poles, and the corresponding rotor current distribution curves, are shown in figure 1, at time intervals of 15 electrical degrees. In the stator winding distribution diagram at the top of the figure, the arrows indicate the positive direction of current in each coil side, not the current distribution at a particular time. The cyclic maximum value of stator current per coil side (turns per coil times maximum stator current per conductor) is denoted by I_s. At the time ($\theta = 0$ degrees) the instantaneous values of currents, indicated in the vector diagram at the left, are:

Phase $A = 0$
Phase $B = -0.866 I_s$
Phase $C = 0.866 I_s$

Using these values with the winding distribution diagram, the curve of stator current distribution, S, is obtained for time ($\theta = 0$). The rotor current distribution curve, R, is drawn so that the total current curve, T, is the sinusoidal equiva-

lent of the stator current curve, that is the fundamental component of the curve S. The amplitude, T_m, may be obtained by use of the formula for the coefficient of the fundamental term of the Fourier series:

$$T_m=\frac{2}{\pi}\int_0^{\pi} S\sin\phi d\phi \qquad (1)$$

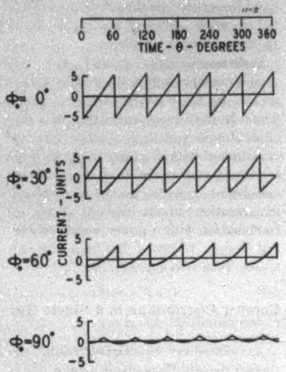

Figure 2. Rotor-bar current at zero slip for three-phase winding with 2/3 pitch

For the time ($\theta=0$) the values of stator current shown give:

$$T_m=\frac{2}{\pi}\left[\int_0^{\pi/3} 0.866I_s \sin\phi d\phi+\int_{\pi/3}^{2\pi/3} 1.732I_s \sin\phi d\phi+\int_{2\pi/3}^{\pi} 0.866I_s \sin\phi d\phi\right]$$

$$=\frac{3\sqrt{3}}{\pi}I_s \qquad (2)$$

and at any other time, the same value will be found for T_m. In figure 1, a value of I_s is chosen arbitrarily to make $T_m=$ ten units, so:

$$I_s=\frac{10\pi}{3\sqrt{3}}=6.05 \text{ units} \qquad (3)$$

and all the curves are drawn to this scale.

The rotor current distribution curves may be used to obtain the time curve of current in a particular bar by following a point on the rotor as it turns with the field. Due to discontinuities in the distribution curves, the time curves of rotor current cannot be obtained by Fourier analysis; however by using the values on the curves in figure 1, the curves of figure 2 may be obtained. The curve ($\phi_0=0$) shows current in the rotor bar which is in position ($\phi=0$) at time ($\theta=0$), so the value 5.24 units is taken at the point ($\phi=0$) on the curve for time ($\theta=0$) in figure 1. At time ($\theta=15$ degrees) the rotor has moved 15 degrees to the right, so the value of rotor current is taken from the ($\theta=15$ degrees) curve at point ($\phi=15$ degrees). The values of rotor current in this bar at $\theta=30$ degrees and 45 degrees are read similarly from the corresponding curves at the 30-degree and 45-degree points respectively. At ($\theta=60$ degrees) the distribution curves are like the ($\theta=0$) curves and the rotor current wave repeats, so the rotor-bar current in this case is a 360-cycle wave of nearly triangular wave shape. The curve ($\phi_0=30$ degrees) in figure 2 is obtained similarly; the first point is taken from the ($\theta=0$) curve at ($\phi=30$ degrees), etc. For different bar positions, the magnitude of this band-frequency component changes as well as the wave shape with a maximum value for the position ($\phi_0=0$):

$$R_b=6.05\sin 60°=5.24 \text{ units} \qquad (4)$$

and only 0.67 unit for the bar in the ($\phi_0=90$ degrees) position.

The curves of figure 2 represent rotor-bar currents in a machine running at synchronous speed. At no load with a small amount of slip, these curves show some of the phases through which the rotor current passes slowly as the bar changes its position with reference to the revolving field.

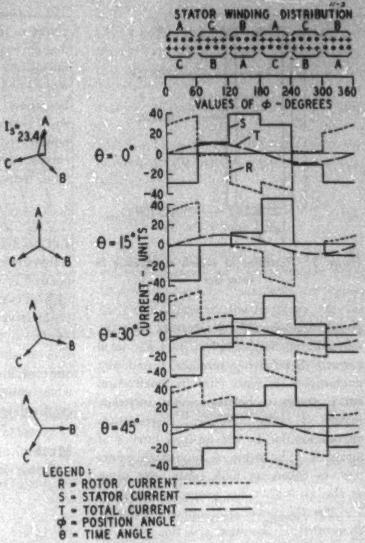

Figure 3. Full-load current distribution curves of three-phase winding with 2/3 pitch

Effect of Load Upon Rotor Current

When the motor is loaded, the stator current is increased by the addition of a

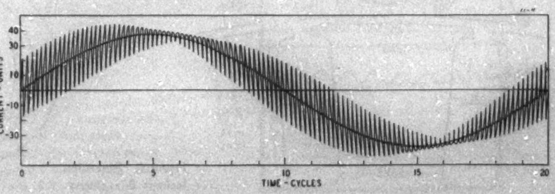

Figure 4. Rotor-bar cunent at full-load with 5 per cent slip, for three-phase winding with 2/3 pitch

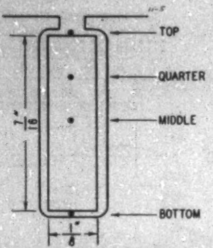

Figure 5. Positions of search conductors in rotor bar

power component in quadrature with the magnetizing component. Since the total current distribution remains practically unchanged, the rotor current distribution curve shows a corresponding increase. Figure 3 shows full-load distribution curves, similar to the no-load curves of figure 1. The value of magnetizing current is taken as 6.05 units, the same as the no-load value given in equation 3. For the power component a value of 22.6 units is assumed, so the value of I_s used in drawing the curves of figure 3 is:

$$I_s = 6.05 + j22.6 = 23.4 \text{ units (at 75 degrees)} \qquad (5)$$

The total current, T_m, equals ten units as before.

The curve of rotor-bar current in figure 4 is obtained from these distribution curves by following a point on the rotor, using a slip of five per cent which corresponds to full load. The rotor current now shows a slip-frequency component with amplitude, R_s, proportional to the power component of stator current:

$$R_s = 22.6 \times \frac{3\sqrt{3}}{\pi} = 37.35 \text{ units} \qquad (6)$$

The band-frequency component increases with the stator current, so the maximum amplitude:

$$R_b = \frac{23.4}{6.05} \times 5.24 = 20.3 \text{ units} \qquad (7)$$

The frequency of this component also changes. At synchronous speed each 60-degree band of the stator winding produces one cycle of the band-frequency wave. As the speed decreases, the band-frequency drops; and for each cycle of slip frequency, the band-frequency component passes through all its phases corresponding to a complete cycle. The band frequency for a value of slip, s, is:

$$f_b = (1-s)6f + sf = (6-5s)f \qquad (8)$$

and at five per cent slip, this frequency is 345 cycles. This band-frequency component is superposed on the sinusoidal (slip-frequency) component; and it passes progressively through the various phases shown in figure 2. In these computed curves the tooth-ripple frequency is omitted, and this should be kept in mind when comparing them with the oscillograms shown later.

Method of Measuring Rotor-Bar Current

In February 1937, an article by Narbutovskih[2] showed a method of obtaining rotor-bar current curves by placing search conductors in the rotor bar. The search conductor is an insulated wire running through the rotor bar under observation, and connected to it at the back end. The front end of the test conductor and the front end of the rotor bar are connected through sliding contacts to the first stage of an amplifier, so no current is drawn from this test circuit. The voltage between the leads is equal to the instantaneous value of iR drop in the bar material adjacent to the test conductor and therefore is proportional to the current density.

The article is most interesting because these oscillograms constitute the first published record of actual rotor-bar currents which has come to the writer's attention. The tests were run on an early type of machine with nearly square rotor bars, and an open slot stator which produced a large tooth ripple in the rotor current. From a study of the oscillograms, it is not apparent that the amplifier used had a frequency range low enough to show slip frequency. The band-frequency component is discernible but is nearly covered up by the large tooth-frequency component.

Preliminary tests showed that this method would permit the study of harmonics in the rotor-bar current, which would be even more interesting in a machine of modern design. An amplifier was constructed with a power stage suitable for direct connection to a magnetic oscillograph; with maximum voltage amplification about 50,000. Used in combination with a power supply of special design, it has a flat-frequency response from 1 to 2,000 cycles.

Current Distribution in a Single Bar

As pointed out by Narbutovskih,[2] the current density throughout a rotor bar is far from uniform, particularly for high-frequency components, due to rotor leakage flux. A search conductor in the rotor bar does not, therefore, measure the current in the bar, but rather the current density adjacent to the test conductor. In a narrow rectangular bar the current density across the bar will be nearly uniform, except for very high-frequency components, but will vary with the depth in the bar. For the tests reported in this paper, four search conductors were used, placed as shown in figure 5. Specifications on the machine tested were:

Rating: 220 volt, 3 phase, 60 cycle, 5 horsepower, 1,800 rpm

Stator: 48 coils, 22 turns No. 15, throw 1-9, connected parallel-wye

Rotor: 45 copper bars, $^1/_8$ by $^7/_{16}$ inch, length 2.38 inches copper end rings, $^1/_4$ by $^{29}/_{32}$ inch, mean radius 2.89 inches

The dimensions of rotor slots and teeth, air gap, and stator slot openings are shown in figure 6, all dimensions in inches.

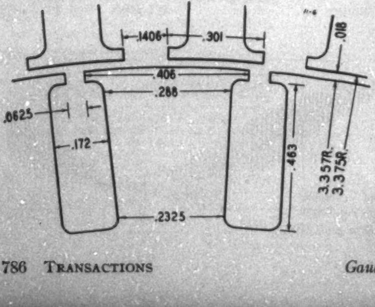

Figure 6 (left). Rotor slot and tooth dimensions

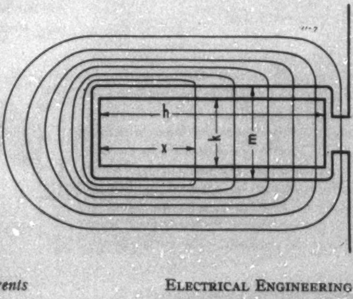

Figure 7. Rotor-bar leakage flux pattern

Figure 7 shows a bar of thickness, k, and depth, h, in a slot of width, m, with all dimensions in inches. Certain simplifying assumptions are made concerning the leakage flux pattern which are quite valid for a narrow rectangular bar nearly filling the slot. Due to the higher reactance of the lower part of the bar, the current density is highest at the top of the bar and diminishes to a minimum at the bottom. Also the current in lower layers is lagging in phase. Both of these effects are most noticeable at high frequency, are relatively small at 60 cycles, and are practically negligible at slip frequency. The current distribution for a particular frequency is given by the formulas:

$$U_x = A\sqrt{2\cosh(2ax) + 2\cos(2ax)} \qquad (9)$$

$$\tan\psi_x = \tanh(ax) + \tan(ax) \qquad (10)$$

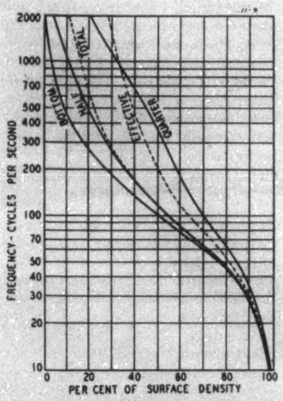

Figure 8. Current density at different levels in per cent of surface density

where U_x is the cyclic maximum current density at a distance, x, from the bottom of the bar.

$$A = \frac{U_h}{\sqrt{2\cosh(2ah) + 2\cos(2ah)}} \qquad (11)$$

where U_h = current density at the top of the bar.

$$a = \sqrt{\frac{1.003kf}{\rho m 10^7}} \qquad (12)$$

ρ = resistivity in ohms per inch cube
f = frequency in cycles per second
ψ_x = phase angle of current at point x with respect to that at the bottom of the bar

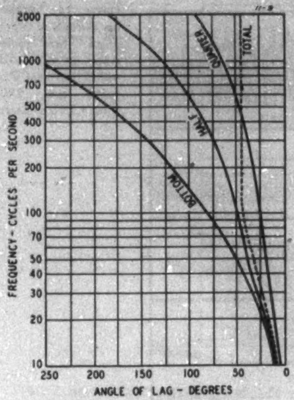

Figure 9. Angle of lag at different levels referred to current at top of bar

In accordance with these formulas, the curves of figure 8 are computed to show the current density at the quarter, middle, and bottom of the bar used, in per cent of the value at the top, for the range of frequencies encountered. Figure 9 shows the angle of lag of the current at the same levels with respect to that at the top of the bar. For the 360-cycle band-frequency component discussed previously, for example, the distribution and phase, taken from these curves, are shown in table I. The current density falls off rapidly with the depth, also the phase shift is large, therefore the average density is only 26 per cent of the density at the surface. The formula for computing this average is:

$$U_{av} = \frac{A}{ah}\sqrt{\cosh(2ah) - \cos(2ah)} \qquad (13)$$

and the phase angle with respect to the current at the bottom of the bar is ψ_{av}, where:

$$\tan\psi_{av} = \frac{\tan(ah) - \tanh(ah)}{\tan(ah) + \tanh(ah)} \qquad (14)$$

It should be noted that the formula is developed in terms of "amperes per bar", that is, the density in amperes per square inch multiplied by the bar area; so the average current density is numerically equal to the total bar current. The formula for effective or rms density, in the same units, is:

$$U_{eff} = A\sqrt{\frac{\sinh(2ah) + \sin(2ah)}{ah}} \qquad (15)$$

These formulas are developed on the basis of sinusoidal wave shape. The band-frequency wave is very nearly triangular so the current density drops a little faster than for a sine wave of the same frequency, due to the higher frequency components of the wave. The wave shape also improves, and becomes nearly sinusoidal near the bottom of the bar. Nevertheless, the curves of figure 8 give a reasonably correct picture of current distribution, especially if a small correction is made for wave shape, and they agree closely with the results obtained by measurements on oscillograms.

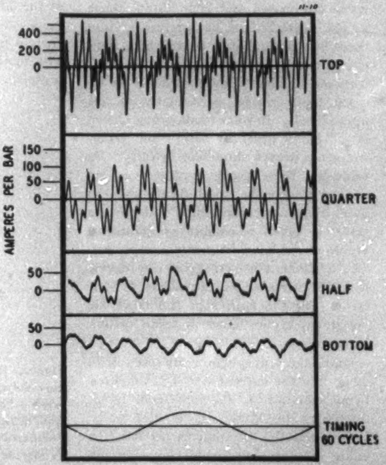

Figure 10. Rotor-bar currents of three-phase four-pole motor at synchronous speed, 1,800 rpm, 220 volts, 3.31 amperes

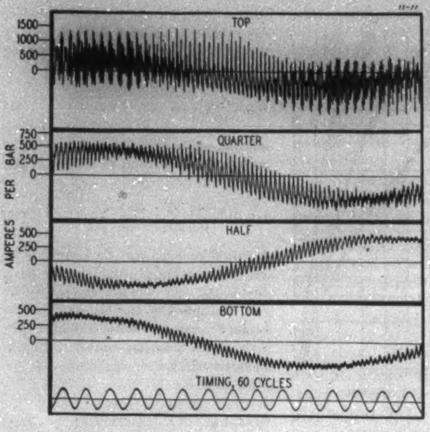

Figure 11. Rotor-bar currents of three-phase four-pole motor at full load with 5 per cent slip 1,710 rpm, 220 volts, 13.15 amperes

Rotor Current Oscillograms

Figure 10 shows rotor current oscillograms for the three-phase motor running at synchronous speed, 1,800 rpm, together with a 60-cycle timing wave. The curves at the different levels in the bar were not actually taken simultaneously, since only one amplifier was used. By means of a stroboscope, the curves were all taken at the same point in the band-frequency cycle; then the waves were lined up on the sheet by means of their separate timing waves, of which only one is shown. By noting the current scales, it is seen how the band-frequency wave diminishes and changes its shape as the depth in the bar increases; also there is a gradual shift to the right, indicating a greater angle of lag. These effects are hidden by the prominent 1,440-cycle tooth ripple, particularly at the upper levels. In some oscillograms shown later, for a different setup, the band-frequency waves show more clearly. In table II, these oscillograph curves are analyzed into the tooth-frequency and band-frequency components. Also in the table is given a column of computed values of the band-frequency component. The agreement is very good considering that the wave shape introduces a little error. All the figures in the table are maximum cyclic values in terms of amperes per bar.

On this test, at synchronous speed, with 220 volts, the current was 3.31 amperes. From equation 4, the maximum band-frequency amplitude, R_b, is 5.24 units. To convert this to amperes per bar, the value of stator maximum amperes per coil side is determined and this is multiplied by the ratio of stator to rotor slots. By equation 3, this is equal to 6.05 units. So:

$$6.05 \text{ units} = \frac{3.31\sqrt{2}}{2} \times 22 \times \frac{48}{45} \text{ amperes}$$

or

$$1 \text{ unit} = 9.09 \text{ amperes per bar} \qquad (16)$$

and

$$R_b = 5.24 \times 9.09 = 47.5 \text{ amperes per bar} \qquad (17)$$

This value appears in table II for "total" current (or average current density). The computed values of current density at the different levels and the "effective" value are figured from this value of total current using the percentages in table I. The tooth-frequency component is more prominent in the top layer, but falls off rapidly. Its effective value is rather hard to determine, but will undoubtedly be lower than that of the band-frequency component in this case.

In figure 11, are shown oscillograms taken under load with readings as follows:

Input—220 volts, 13.15 amperes, 4,570 watts
Output—5.03 horsepower, 1,710 rpm

No attempt has been made to line up this series of oscillograms with the single 60-cycle timing wave shown, and this is included merely to give the time scale which is the same for all curves. A little over one-half cycle of the three-cycle slip-frequency wave is shown at all four levels. As before, the tooth-frequency wave masks the band-frequency wave at the top of the bar. But at the quarter level, and especially at the middle of the bar, the tooth ripple is small and the band-frequency wave is quite prominent; also the similarity between these curves and the computed wave of figure 4 is very marked. The cyclic maximum values of the various components, scaled from these oscillograms, are given in table III.

To check the computation of band-frequency components, from equations 16 and 17 a stator current of 3.31 amperes gives $R_b = 47.5$ amperes per bar. Since this component varies directly with stator current, the value for the "total" under load is:

$$R_b = 47.5 \times \frac{13.15}{3.31} = 189 \text{ amperes} \qquad (18)$$

The maximum values at various levels are computed from this using the percentages of figure 8 for a frequency of 345 cycles. The computed magnitude and distribution of band-frequency current agree very well with the values measured on the oscillograms. Also the effective value of this component is of the same order of magnitude as the slip-frequency component.

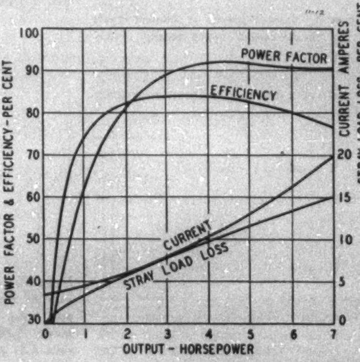

Figure 12. Load-test curves of squirrel-cage motor rated 5 horsepower, 1,800 rpm, three-phase 220 volts. Temperature 55 degrees centigrade

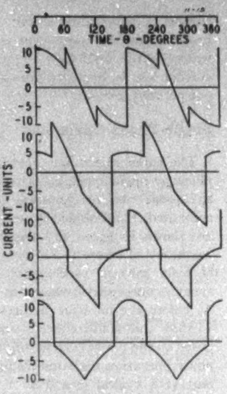

Figure 13. Rotor-bar current at zero slip for single-phase winding with 2/3 pitch

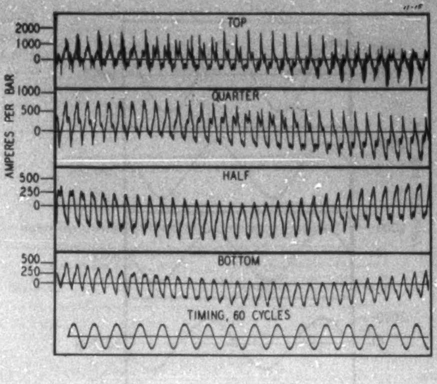

Figure 15. Rotor-bar currents of single-phase four-pole motor with 3.6 per cent slip

The slip frequency is only three cycles, so the value of this component at various levels should be the same as the total. This fact is clearly shown in the oscillograms, although the magnitude does not check so well. The slip-frequency component of rotor current is in space phase with the total magnetomotive-force wave, and is computed from the power component of stator current. The maximum value of this is approximately:

$$\sqrt{2}\times\sqrt{13.15^2-3.31^2}=12.72\sqrt{2}$$
$$=18 \text{ amperes} \qquad (19)$$

The corresponding rotor-bar current, by equations 1 and 2, is:

$$R_s=\frac{3\sqrt{3}}{\pi}\times\frac{18\times 22}{2}\times\frac{48}{45}=350 \text{ amperes} \qquad (20)$$

As a further check upon the magnitude of the slip-frequency component, the slip-frequency loss was computed, also the total resistance per bar. The stator resistance between terminals was 1.139 ohms at 55 degrees centigrade, so the stator copper loss was 295 watts. The fixed loss was 220 watts. Therefore:

$$\text{Rotor input}=4{,}570-295-220=4{,}055 \text{ watts}$$

$$\text{Slip-frequency loss}=\frac{90\times 4{,}055}{1{,}800}=203 \text{ watts} \qquad (21)$$

The total rotor resistance per bar at 55 degrees centigrade is:

$$r=69\times 10^{-6} \text{ ohms} \qquad (22)$$

The amplitude of the slip-frequency component of current, then, computed from the value of loss shown in equation 21 is:

$$R_s=2\times\frac{203\times 10^6}{45\times 69}=359 \text{ amperes} \qquad (23)$$

and this result checks very closely with the value shown in equation 20, but is 13 per cent less than the value scaled from the oscillograms, as shown in table III. This may indicate an error of approximately 15 per cent in the computed scale of the oscillograms, in spite of the care taken to obtain an accurate calibration.

Effect Upon Motor Efficiency, Stray Loss

The total loss determined by the conventional method of losses is:

$$295+220+203=718 \text{ watts} \qquad (24)$$

But the total loss determined by a careful dynamometer test is:

$$4{,}570-3{,}750=820 \text{ watts} \qquad (25)$$

The stray loss at this load therefore is:

$$820-718=102 \text{ watts} \qquad (26)$$

which is over two per cent. Performance curves for this motor are shown in figure 12, including a curve of stray loss in per cent of input. The shape of this curve is in substantial agreement with other published material.

Several writers on the subject of stray-load loss in induction motors agree that the loss is largely due to high-frequency flux pulsations in the stator teeth, plus a relatively small tooth-frequency eddy-

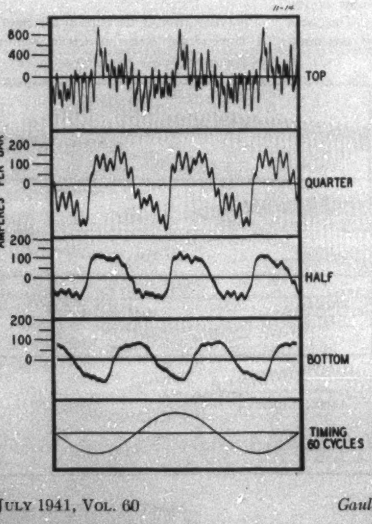

Figure 14. Rotor-bar currents of single-phase four-pole motor at synchronous speed, 1,800 rpm, 220 volts, 5.13 amperes

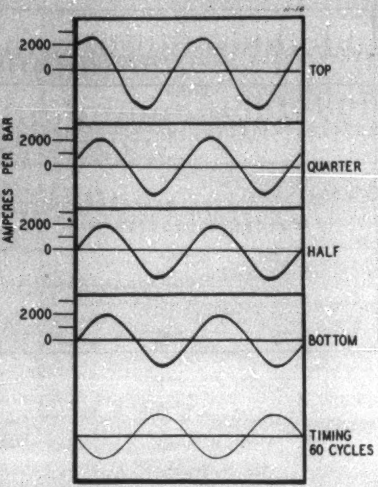

Figure 16. Rotor-bar currents of single-phase four-pole motor with rotor locked, 220 volts, 47.6 amperes

current loss in the rotor bars. In the tests reported herewith, the tooth-frequency eddy-current loss was found to increase with load. The lower frequency band-frequency eddy-current loss was found to be of even greater importance. At full load, this component (see figures 4 and 11) has a frequency of 345 cycles, and its amplitude rises and falls with a beat frequency of $2fs=6$ per second. The rms value of this component per bar is computed to be:

$$I_b=\frac{U_{eff}}{2.38}=\frac{304}{2.38}=128 \text{ amperes} \quad (27)$$

Table I. Current Distribution and Phase for 360-Cycle Component

Level	Current Density (Per Cent)	Angle of Lag (Degrees)
Top	100	0
Quarter	50.1	39.1
Middle	24.2	79.3
Bottom	13.4	155.0
Average (total)	26.0	45.3
Effective	42.6	

Table II. Rotor-Bar Current Distribution in Figure 10

Level	Tooth-Frequency 1,440 Cycles	Band-Frequency = 360	
		Measured	Computed
Top	350	187	183
Quarter	33	55	91
Middle	10	30.5	44
Bottom	3	20	24.5
Total			47.5
Effective			78

Due to the distribution of this component in the end rings, the loss there is very small, and the resistance per bar may be taken as 34×10^{-6} ohms instead of the value given in equation 22. The rotor loss produced by this component therefore is:

$$W_b=45\times(128)^2\times34\times10^{-6}=25 \text{ watts} \quad (28)$$

This is about a quarter of the stray load loss.

In table III is shown a value of 225 amperes for the peak rms value of the tooth-frequency component. This was computed from the curve of measured current density values shown. The loss produced by this component is about 15 watts, so the total high-frequency rotor current loss is 40 watts, which is nearly one per cent of input.

Single-Phase Operation

The same motor was operated single phase by opening one line after it was up to speed. At synchronous speed the computed band-frequency wave shapes are shown in figure 13; the underlying frequency of course is 120 cycles. A set of rotor current oscillograms taken at synchronous speed is shown in figure 14. As before the full-load pictures of figure 15 show the band-frequency wave superposed on the power current, but for single-phase operation the band-frequency current (118 cycles) is a little larger than the slip-frequency current (2.2 cycles).

A locked test was also run on this motor connected single phase, and oscillograms are shown in figure 16. At standstill, all frequency components reduce to 60 cycles, giving a sine wave of current in the rotor bars. The shift in phase is shown by the drift to the right at the lower levels. Values of current density and phase angle with respect to the current at the top are shown in table IV; measured values taken from the film are compared with computed values. The check on phase angle is quite close. There is a satisfactory qualitative check on amplitude also, but the measured values seem to be too high, as noted previously in table III.

Consequent-Pole Winding

By reconnecting the coils of this motor, a three-phase consequent-pole winding

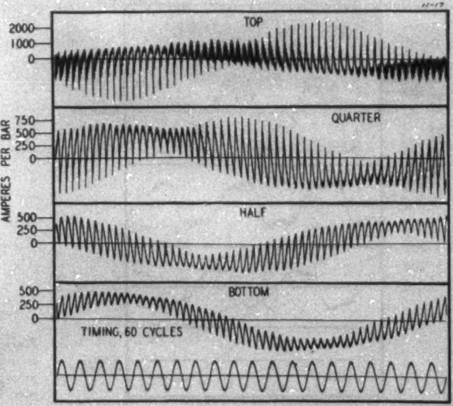

Figure 17. Rotor-bar currents of three-phase four-pole motor, consequent-pole connection 1,710 rpm, 190 volts, 14.4 amperes

Bottom	1,870	1,530	57.3	57.9
Total		1,578		35
Effective		1,675		

was produced with eight coils per phase group for four-pole speed, that is using a phase band width of 120 degrees instead of 60 degrees and only two polar groups per phase. Upon analysis this gave a band-frequency wave similar to that shown in figure 2, but of half its frequency (180 cycles at synchronous speed) and approximately twice its amplitude. This is noted in the load oscillograms of figure 17. The load-test curves of figure 18 show decreased efficiency, particularly at heavier loads, and a considerable increase in stray-load loss, due almost entirely to the larger band-frequency current in the rotor bars. The test was run on 190 volts to get the same flux density in the motor.

Eight-Pole Operation

The stator winding was reconnected for three-phase eight-pole operation. Using the same coils as before, the coil pitch is four-thirds, which produces a band-frequency wave like that in figure 2; so the load oscillograms shown in figure 19 are quite similar to those in figure 11 except that the tooth ripple is almost entirely gone.

Conclusions

High-frequency components in the rotor-bar current may contribute a considerable portion of the stray-load loss in a squirrel-cage motor. By proper slot design, the tooth-frequency component may be controlled. The band-frequency component, however, depends upon the winding, and may be decreased by co-ordinating pitch and number of phases. If a pitch of five-sixths instead of two-thirds had been used with the three-phase four-pole winding, the band-frequency wave would be as shown in figure 20 instead of that shown in figure 2. An analysis of this wave shows a band-frequency current loss of about one-third as much.

Classification and Co-ordination of Short-Time and Intermittent Ratings and Applications

R. E. HELLMUND
FELLOW AIEE

Synopsis: The paper makes a comparison of permissible temperature rises for short-time and intermittent ratings and permissible rises for continuous ratings. It suggests methods for the application of short-time ratings to various typical classes of intermittent load conditions and presents for each of these classes ways and means for properly co-ordinating the ratings of the major devices (motors and generators) and the ratings of the auxiliary devices and conductors.

Introduction

THE present commercial standards for electrical apparatus and conductors usually provide continuous ratings and short-time ratings for periods of 5, 15, 30, 60, and 120 minutes. The methods used for selecting ratings for various classes of intermittent or varying loads from these available ratings are rather indefinite and at times result in applications which, although generally satisfactory, are often not the most economical. It is shown in this paper that by following essentially the present practices of rating and application but also properly co-ordinating them and supplementing them with additional data, a selection of the most suitable short-time ratings can be made. A very simple procedure applying to the proper co-ordination of the main apparatus and the auxiliary devices and conductors is outlined at the end of the paper. To facilitate this co-ordination, standard temperature-rise values which seem suitable for short-time ratings of the main and auxiliary apparatus and conductors are derived and tabulated.

Short-Time Ratings and Loads

In many standards the short-time ratings are based on temperature rises higher than those on which the continuous ratings are based. Although the differences between the values for short-time and continuous ratings generally were selected arbitrarily, the basic principle of having a difference between them is sound. With short-time loads the maximum temperatures obtained can last for only a relatively small part of the total time. Since the deterioration of insulation depends not only upon temperature but also upon the length of time the higher temperatures prevail, satisfactory life can be obtained if relatively high temperatures prevail for only a small part of the time. Tests have indicated that the life of insulation is halved for each eight- to ten-degree-centigrade increase in temperature, particularly for insulation exposed to oxygen in the air. It is proposed to use this rule here and to calculate for some typical short-time ratings the permissible maximum temperature rises which result in insulation life about equal to that obtained with temperatures specified as standard for continuous operation. (Methods suggested by V. M. Montsinger for transformers[1,2] and also outlined by P. L. Alger and T. C. Johnson[6] will be used for this purpose. These methods and the eight- to ten-degree-centigrade value may not apply to applications where oxygen is excluded, as in oil-insulated transformers with inert air protection or hydrogen-cooled machines.)

Figure 1 shows a number of typical time-temperature curves for short-time ratings of a small induction motor. These curves have been calculated under the assumption that each eight-degree-centigrade increase in temperature halves the life of the insulation. On this basis, each of the curves shown will give insulation life equal to that obtained with a uniform rise of 60 degrees centigrade (by resistance) over the same period of time. Since the cooling curves approach the zero temperature line asymptotically (reaching zero after an infinite time), it was necessary to limit arbitrarily the time for each curve, and the point at which the temperature rise drops to ten degrees centigrade was taken. This provides a margin of safety and results in conservative curves. (All calculations and discussions in this paper deal with temperature rise by resistance; the thermometer method is not very satisfactory for the study proposed.)

It is seen from figure 1 that the permissible temperature rises range from 80 to 93 degrees centigrade, or an excess of 33 to 55 per cent over the 60-degree temperature rise permissible for continuous operation.[10] The use of these higher permissible temperature rises is of importance economically because, according to curve 1, a five-minute rating with a 60-degree limit can be raised to an 11-minute rating for the higher temperature. Similarly, curve 2 shows an increase from a 15-minute to a 46-minute rating; curves 3 and 4 show increases from 30 to 80 minutes and from 38 to 116 minutes respectively. Curve 4 has been chosen as a limiting case with a rate of temperature rise of about one-half degree a minute at 60 degrees centigrade; for major devices such as generators, motors, etc., it is customary to apply continuous ratings rather than short-time ratings if the rate of temperature rise is lower.

The curves of figure 1 are typical of most apparatus, the principal difference being that with larger devices the time values increase. This, however, does not affect the values of the maximum permissible temperatures, which are influenced essentially by the shapes of the curves and which vary to some extent with different types and sizes. Allowing for such variation within usual limits, it seems safe to select for standardization purposes temperature rises 25 to 40 per cent higher for short-time ratings of major devices than for continuous ratings. Table I, column 2, suggests standard values of temperature rise for short-time ratings of major devices corresponding to the values for continuous ratings in the first column. The values are conservative and higher values might be justified. (After testing class *B* insulated d-c motors for short-time ratings now based on 75 degrees temperature rise by thermometer, F. A. Compton recommends a temperature rise of 105 to 120 degrees centigrade by resistance,[8] the table gives 100 or 110 degrees centigrade.)

The considerations thus far can be applied to any type of apparatus or conductors within the limits stated. (Naturally modifications in some of the values mentioned must be made when values

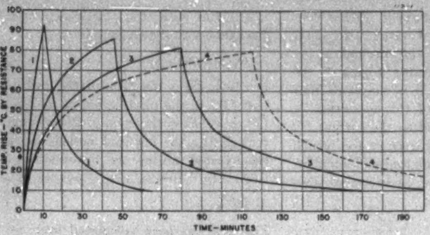

Figure 1. Permissible temperature rises for various short-time loads

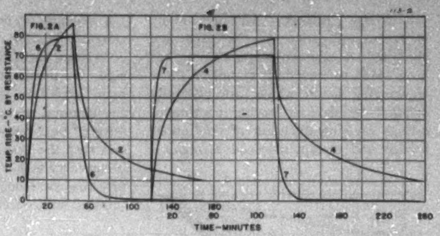

Figure 2. Comparison of permissible temperature rises for short-time loads of apparatus with different time constants

other than 60 degrees permissible temperature rise for continuous load apply.) However, if the main devices are connected in series with various auxiliary devices or conductors having much smaller time constants than the main device, the conclusions derived so far must be modified for the auxiliary devices or conductors. This is demonstrated in figure 2*a*, curve 2 of which corresponds to curve 2 of figure 1 and is considered representative of main devices such as generators, motors, etc. Any smaller device or conductor connected in series with the main device and having a smaller time constant will show more rapid initial temperature rise, and if loaded as long as the main device, will run at temperatures near the maximum for longer periods than the main device. This in turn means that to get equally satisfactory insulation life the maximum temperature-rise values must be kept lower. Curve 6, figure 2*a*, applies to an auxiliary device with a small time constant giving the same insulation life (with the same class of insulation) assumed for the main device. It is seen that 80 degrees centigrade is the maximum permissible value for the auxiliary device instead of 86 degrees centigrade indicated for the main device. Curve 4 in figure 2*b* corresponds to curve 4 in figure 1 and is another typical curve for the main device. Curve 7 has been calculated for an auxiliary device with a smaller time constant to give the same insulation life. Again a smaller maximum temperature rise (71 degrees centigrade) must be chosen for the auxiliary device than the 80 degrees for the main device. Here the auxiliary device reaches constant temperature during the load period.

Table I. Suggested Relation of Temperature Rises (by Resistance) for Short-Time Ratings to Rises for Continuous Ratings

Continuous Ratings (Deg C)	Short-Time Ratings (Deg C) Main Apparatus	 Small Auxiliary Apparatus or Conductors*
20	25	25
25	30 or 35	30
30	40	35
40	50 or 55	45 or 50
50	60 or 70	55 or 60
60 (class *A* insulation)[10]	80	70
80 (class *B* insulation)[10]	100 or 110	90 or 100
100	125	110 or 125

The values in this table are chosen from the preferred values suggested in AIEE Standard number 1.[10] In general they should give satisfactory life of insulation if the rated load is continually reapplied after the apparatus temperature has dropped to about ambient temperature. Practical cases of application of this kind are rare. As a rule, considerable time elapses between the applications of loads, and whenever this is the case the application of apparatus can be made so as to reach even higher temperature-rise values than those suggested for standard rating purposes in the table. Although the value of 80 degrees centigrade suggested in the table to correspond to 60 degrees rise for continuous load does not take full advantage of the permissible rises indicated in figure 1, the increases in time over the 60-degree values are still appreciable, ranging from 65 to 250 per cent.

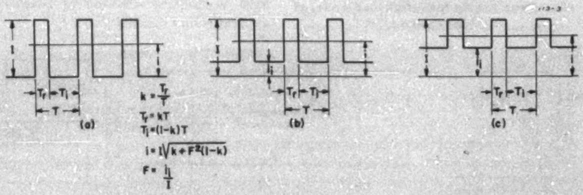
*These values also may be used if the short-time operation of small auxiliary apparatus or conductors results in the same temperature rise obtained with continuous operation at the same load.

In view of the conditions just described, it seems advisable to use lower maximum values of temperature rise for the rating of small auxiliary devices and conductors intended for short-time service. This practice need not be altered by the fact that, as in figure 2*b*, the short-time ratings of the auxiliary devices or conductors give the same temperatures as obtained with continuous operation at the same load. The values in column 3 of table I are suggested for the standardization of small auxiliary devices and conductors used in conjunction with main devices in short-time service. In general, where two values are given, the lower value of one column should be used with the lower value of the other column.

Intermittent and Varying Loads

Typical intermittent and varying load cycles are illustrated in figure 3. During the time (T_r) the apparatus is heavily loaded and carries a current (I), while for the remaining period (T_l) it may carry no load, as in the case of a welding generator[9] (figure 3*a*). Figure 3*b* represents such apparatus as a-c induction motors, which are loaded during the period (T_r) and not loaded during (T_l), but which have to carry a magnetizing current (i_l) during the off periods. There is little change in principle if the motor, instead of carrying a magnetizing current, carries a light load (i_l) as indicated in figure 3*c*. This might occur with an industrial mill which is driven light during (T_l) and loaded during (T_r). In all the applications cited, the rms current (i) is, of course, less than the current (I) during the heavy-load period. (In this discussion, service conditions as illustrated in figures 3 and 10 are of the type which as a rule can be handled by devices having

Figure 3. Typical intermittent and varying (periodic) load cycles



"short-time" ratings. Although many of the considerations in the paper are applicable to other cases, no attempt has been made to include a complete study of varying loads which are generally handled by devices having continuous ratings or a combination of continuous ratings and certain overload ratings.)

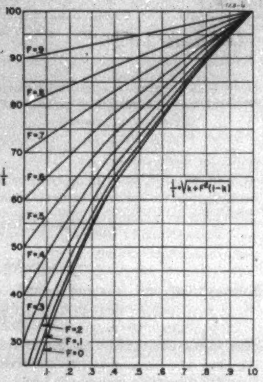


Figure 4. Ratio of rms current to load current for intermittent and varying load cycles

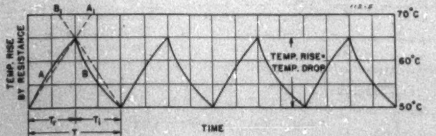
Very often the current (I) during the load period is a significant value in machine design for considerations other than heating. A commutator machine, such as a welding generator[3] for instance, must be able to commutate the current (I) satisfactorily during long periods of machine operation. In an induction motor the value (I) is equivalent to a torque required for driving the load and it is necessary that the pull-out and starting torques of the motor have certain definite relations to the running torque if satisfactory operation and a sufficient margin of safety are to be obtained. Again, the value (I) may be of significance in the regulation of the machine or apparatus. In these examples, current (i) is of importance only in the heating of the machine, while current (I) has considerable bearing on various other characteristics, including the mechanical design. It should therefore appear in the rating structure and it is suggested that the nominal rating of the apparatus be selected to correspond to the current (I) and that the heating current (i_h) which it can carry within safe limits of temperature rise continuously, be indicated by a suitable service factor

$$S_1=\frac{i_h}{I} \tag{1}$$

This has been previously suggested by others (Alger,[4,6] Johnson,[5,6] and Hildebrand[7]) and seems to be a simple method for supplying fairly complete information about heating as well as other characteristics of practical importance. It has also been suggested that no reference whatsoever be made to temperature conditions in connection with the nominal rating corresponding to current (I).[6] However, since practically all nominal ratings of electrical apparatus are now tied in with temperature considerations in some way or other, it seems desirable to retain the temperature rating as the primary basis for all nominal ratings. This can very readily be done because current (I), although it cannot be carried continuously with many devices, can always be carried for at least limited periods and be tied in with one of the standard short-time (5-, 15-, 30-, 60-, or 120-minute) ratings. In this way the length of time the machine can carry the current (I), starting with the machine cold, is indicated. This additional information makes it possible to select for all applications the proper wiring and devices connected in series with the main apparatus, which is very essential for an economical and successful combination of all parts of the circuit. (If the conditions are such that any of the factors, such as commutation, torque, regulation, etc., call for a main device which can carry the current (I) continuously, it can be given a continuous rating (I) and the methods described here will then be of no practical importance with reference to the main apparatus. However, they may be of assistance in the most economical selection of auxiliary apparatus and conductors.)

Figure 5. Temperature variation with intermittent and varying (periodic) load cycles of long duration



The rms current (i), dependent upon the load cycles shown in figure 3, is

$$i=I\sqrt{k+F^2(1-k)} \tag{2}$$

in which (k) is the ratio of the load period (T_r) to the total period of the cycle (T), and (F) is the ratio of the rms current during the low-load periods to the rms current during the heavy-load periods. In figure 3a, with $F=0$, we have

$$i=I\sqrt{k} \tag{3}$$

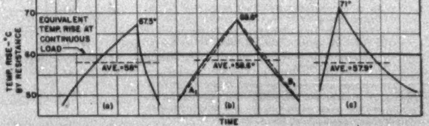
Figure 4 has been calculated from formula 2 and gives the rms current for any value of k and F.

With the regularly repeating (periodic) load cycles shown in figure 3, it is evident that the drop in temperature during each light- or no-load period must at least equal the rise in temperature during each heavy-load period in order to obtain a stable cyclic temperature condition in which permissible temperature values are not exceeded. (See figure 5.) It follows directly that with a heavy-load period (T_r), a time (T_l) must be allowed for the light- or no-load period, resulting in a total time (T) for each cycle. With the time-temperature curves A and B fixed by the loads and apparatus characteristics, the maximum ratio of $T_r/T=k$ is definitely limited. It is dependent upon the ratio (R) of the average rate of drop (B_1) to the average rate of rise (A_1) and follows from

$$k=\frac{R}{1+R} \tag{4}$$

These relations are basic to all regularly repeating (periodic) intermittent or varying loads. A more complete outline of this method of analysis by time-temperature curves is given in a previous paper.[3] In that paper it was generally assumed that the peak temperature rises reached with short-time ratings and during intermittent loads should be the same as the permissible temperature rises for continuous loads. This, however, does not take advantage of the fact that the latter temperature may be safely exceeded for limited periods. An attempt will therefore be made in the following to take advantage of this possibility for

Figure 6. Permissible temperature rises for typical periodic loads



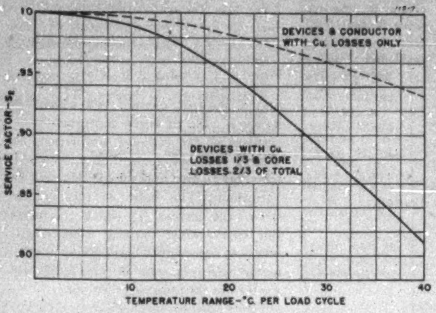


Figure 7. Service factor S_2 takes into account the amplitude of the cyclic temperature variation

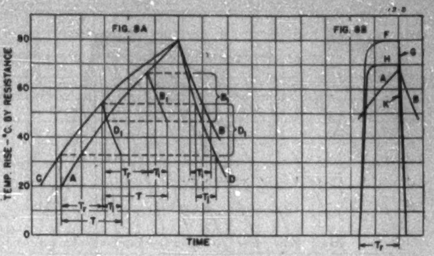

Figure 8. Comparative analysis of temperature conditions for apparatus of different time constants during periodic load cycles

intermittent load applications as in figure 5.

Class 1A Intermittent Service

For this class of service it is assumed that the ventilation conditions are not appreciably changed between the heavy-load and the light- or no-load periods. This applies to most stationary devices or conductors unless they are equipped with adjustable forced ventilation; it also applies in general to constant-speed machinery while running. It is further assumed that the load periods are rather short and the variation in temperature rise will be so small that it can be neglected.

Since with these assumptions the temperature of the machine is about constant, the value (i) should be such as to give a safe temperature rise for continuous operation. For this type of service it is therefore necessary merely to select apparatus having a short-time nominal rating (I) with a service factor at least equal to

$$S_1 = \frac{i}{I} = \frac{i_h}{I} \qquad (5)$$

The method outlined under class 1*A* should be satisfactory if its use is confined to applications where the heavy-load period is limited to ten per cent of the time (T_s) on which the nominal rating is based; that is, in the case of a 30-minute rating, for instance, the load period (T_r) does not exceed three minutes. Then the total temperature variation during the cycle will as a rule be less than ten per cent of the temperature rise for continuous operation and the excess temperature will be less than five per cent.

The wiring and auxiliary devices connected in series with the main machine or apparatus usually have smaller time constants. Therefore, their temperature variations in percentage of the average temperature rise during the time periods just indicated may be larger. This makes it advisable to select them for a continuous rating five to ten per cent larger than the rms value of the load.

Class 2A Intermittent Service

For class 2*A* applications, it is assumed that the cooling conditions are essentially the same during the entire load cycle but that the time for each cycle is increased to the point where the variations in temperature can no longer be neglected. Figure 6 shows three typical time-temperature curves, each for a single cycle with a total temperature change of 20 degrees centigrade. These curves also have been calculated to give a life of insulation equivalent to that obtained with continuous operation at 60 degrees centigrade rise. Figure 6*b* has a curvature in the rising curve about equal to that of the dropping curve. This means that the results are the same as they would be with the triangular time-temperature curve A_1B_1. The maximum permissible temperature rise is 68.6 degrees centigrade. With curves 6*a* having more curvature in the rising curve and thus giving longer periods for the higher temperatures, the maximum must be kept lower, that is to about 67 degrees centigrade. The opposite condition shown in 6*c* led to a higher maximum of 72 degrees centigrade. The average of the temperature rises for these cycles varies within the narrow range of 57.9 to 58.6, that is, 1.4 to 2.1 degrees centigrade, or 2.3 to 3.5 per cent below the temperature-rise value for continuous load. Thus, in order to obtain satisfactory operation the losses must be lowered 2.3 to 3.5 per cent. In devices having only copper losses, this means a reduction of only 1.1 to 1.7 per cent in rms current. In machines designed for intermittent service the core losses are often relatively high, and therefore the copper losses may be as low as one-third of the combined losses. The same reduction in total losses may therefore require a reduction of about 7 to 10.5 per cent in the copper losses, which means 3.5 to 5.5 per cent reduction in the rms current. This is too liberal because the influence of the core losses upon the copper temperature is usually much less than that of the copper losses. It would thus seem that an allowance of five per cent, or a service factor $S_2 = 0.95$, to cover the difference between case 1*A* and 2*A* would be quite safe for a variation of 20 degrees centigrade. The curve for S_2 in figure 7 has been based on this line of reasoning and covers the range of temperature variations usually found in practice.

Determination of the exact temperature variation would require a complete time-temperature curve analysis. It can be safely assumed, however, that it usually does not exceed the value $r(T_r) \div (T_s)$ in which T_r = the time of heavy load per cycle, T_s = the time used as a basis for the short-time rating, and r = the temperature rise upon which this rating is based. It is thus possible to calculate safe maximum limits for the temperature variation and then find the value S_2 for this cycle from figure 7. The service factor for class 2*A* applications is then

$$S = S_1S_2 \qquad (6)$$

The application of smaller auxiliary devices and conductors with main devices in intermittent service of this class cannot be made safely by the method outlined under class 1*A*. Depending upon their time constants, the temperature

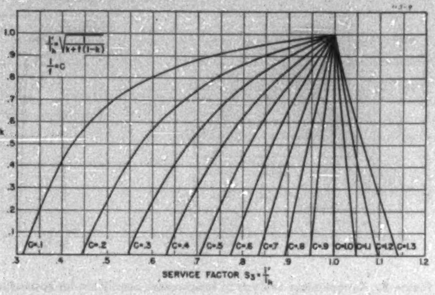

Figure 9. Service factor S_3 takes into account variations in ventilation during the load cycle

rises of the auxiliary devices and conductors may vary over wide ranges and it is hardly feasible to set any safe practical limits for the variation.

Two distinctly different typical conditions are shown in figure 8. In figure 8*a* we have heating curve *A* and cooling curve *B* for a main device. An auxiliary device with smaller time constant and designed for the same short-time temperature rise will have a flatter curve (*C*) for the upper part of the heating curve, and a steeper curve (*D*) for the cooling curve. With a load time (T_r) and idle time (T_i), stable repeating conditions are obtained with a maximum temperature rise of 68 degrees centigrade for the main device and 54 degrees centigrade for the auxiliary device, as found by the methods described in a previous paper.[3] It follows that with conditions shown in figure 8*a*, the auxiliary device will have lower temperature rises than the main device if based on the same temperature rise for the same short-time rating.[9] Entirely different results are obtained if the time constant of the auxiliary device or conductor is so small that maximum temperature is reached during the time (T_r), as shown by curve *F*, figure 8*b*. It is at once evident that with curves *F* and *G* of the auxiliary device or conductor, insulation life will be shorter than with curves *A* and *B* of the main device. This undesirable condition can be largely eliminated by lowering the rating temperature of the auxiliary device or conductor as suggested under short-time ratings in column 3, table I and illustrated by curves *H* and *K* in figure 8*b*. It can therefore be concluded that for intermittent service of this 2*A* class, the auxiliary devices and conductors having the same short-time ratings as the main device can be selected if ratings are based on

(*a*). The same temperature rises (column 2, table I) as the main device, if the auxiliary device does not reach its maximum temperature during the load period (T_r);

(*b*). A somewhat lower temperature rise (column 3, table I) if the auxiliary device reaches its maximum temperature during the load period (T_r).

In general, conditions under (*a*) will apply to all except very small auxiliary devices, while conditions under (*b*) may be found to apply frequently to conductors. If suitable temperature rises, as indicated here, are used in the standardization of devices and conductors for intermittent service, their application becomes exceedingly simple and consists merely in combining apparatus and conductors having the same short-time rating with reference to current and time.

Class 1B Intermittent Service

In some classes of application, ventilation conditions are considerably different during the periods of heavy and light load or no load. This is true in any case where artificial cooling is automatically stopped, except during the heavy-load period. A more common application is represented by motors carrying a current (*I*) while loaded and running and which stand still during idle periods. In these applications the rate of cooling is usually reduced because of the reduced ventilation, although with motors standing still this is at least partially compensated by the absence of those losses (essentially core losses) occurring with the motor running light. In some applications, especially enclosed motors, the elimination of losses may more than counteract the reduced cooling.

If the ratio of the cooling rate for class 1*A* to that for class 1*B* during no-load periods is assumed to be (*f*), it follows that the necessary drop in temperature for each cycle can be obtained for class 1*B* if the no-load time is increased from T_i to $T_i^1=fT_i$. Consequently, we can analyze class 1*B* applications the same as class 1*A* merely by substituting the time (T_i^1) for (T_i). By replacing in formulas 2 and 3 the value *k* by $k^1=\frac{T_r}{T_r+T_i^1}$, we find a reduced current (i^1) which the motor is able to carry continuously regardless of the reduced ventilation, assuming that the total time per cycle is too short to give appreciable temperature variations. The ratio of this current (i^1) to the current (i_h) which the motor can carry while running continuously may be represented by another service factor (S_3). It can be calculated for $F=0$ from the following formula

$$S_3=\frac{i^1}{i_h}=\sqrt{\frac{T_r+T_i}{T_r+fT_i}}=\sqrt{\frac{1}{k+f(1-k)}} \tag{7}$$

Figure 9 gives this service factor for various values of *k* and *f*. With the aid of these curves the current (i_h) can be found directly from the smaller actual rms current (i^1). The total service factor for class 1*B* applications is, therefore, $S=S_1S_3$. Suitable values for (*f*) can be determined by the test method described in a previous paper,[3] taking cooling curves with the motors running and at rest. The method here outlined for class 1*B* motors should be satisfactory if the running time per cycle does not exceed ten per cent of the rating time (T_s).

The application of conductors and auxiliary devices follows the same general principle as suggested for class 1*A*, using the actual rms current as a basis. This, of course, is under the assumption that the cooling conditions of the conductors and auxiliary devices are the same for both the load and the idle period, which is generally true.

Class 2B Intermittent Service

For class 2*B* applications it is assumed that the ventilation is different for the high-load and the low-load or no-load periods, but that the time for each load cycle is so long that temperature variations become of practical importance. Thus, class 2*B* applications have the same relation to class 1*B* as class 2*A* have to class 1*A*. It is therefore necessary to introduce, in addition to the service factor (S_3), the service factor (S_2), which leads to the service factor

$$S=S_1S_2S_3 \tag{8}$$

If auxiliary devices and conductors are combined in this service with the main devices by the methods suggested for class 2*A* applications, they will as a rule have an unnecessarily large margin of safety. The reason for this is that the cooling conditions of the auxiliary devices and conductors usually remain unchanged, while those of the main device are reduced during the ideal periods. However, it is not safe to suggest any other practice which is generally applicable. In specific applications, with known conditions and additional analysis, further economies may be accomplished, but as a rule the gains possible will be of minor importance in the total cost.

General Discussion of Service Factors

S_1 indicates the ratio of the current giving a safe temperature rise with continuous operation to the current corresponding to the nominal (short-time) rating. It is governed by the design of the apparatus and the temperature rises used as a basis for short-time and continuous ratings; it must be determined by test. Minimum values for (S_1) should be known and be standardized for certain types, classes, and ranges of ratings, the same as is done with torque ratios. This is exemplified in table II.

Table II

5-minute ratings	$S_1 = 0.50$
15-minute ratings	$S_1 = 0.60$
30-minute ratings	$S_1 = 0.70$
60-minute ratings	$S_1 = 0\ 80$
120-minute ratings	$S_1 = 0.87$

S_2 makes allowance for temperature variation during long load cycles. It is governed partly by the type of application and partly by the design of the apparatus. However, since it does not vary widely, it can be shown with sufficient accuracy for most practical purposes by curves as shown in figure 7. As pointed out there, higher values than those indicated for S_2 in the full-line curve apply to cases where the copper losses essentially govern the temperature rise of the windings (dotted curve in figure 7).

S_3 makes allowance for differences in ventilation which may exist between the heavy-load and the light- or no-load periods. It is influenced by both the type of application and characteristics of the apparatus. The influence of the former is covered in formula 7 by the factor (k) determined from the service condition. The factor (f), depends upon the apparatus characteristics. It is not recommended here that (f) be made a part of the rating structure but that for various types of motors, values for (f) be established which are safe but which do not result in uneconomic applications.

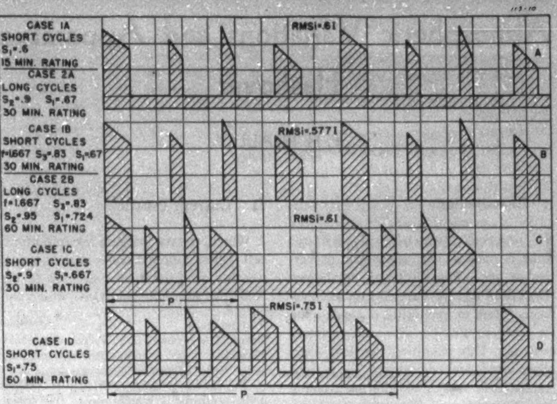

Figure 10. Some typical load cycles analyzed by the methods suggested

Selection of Short-Time Ratings for Intermittent or Varying Loads

(a). Main Apparatus

The variety of conditions met in practice makes it impossible to outline a method of application suitable under all circumstances. However, the data presented here are suitable for the majority of applications and should prove helpful in giving results quickly. Both periodic load cycles as shown in figure 3 and load cycles with irregular intermittent loads as in figure 10 can be calculated as follows.

Divide the entire time into high- and low-load or no-load periods; then calculate the rms current for all the high-load periods. The resultant value is the current (I) of our previous analysis and it is used for the selection of the current value of the nominal short-time rating (or horsepower or kilowatt ratings corresponding to this current value).

The current value (i_r) previously used is found by calculating the rms current for all the low-load periods and it permits the calculation of $F = i_r/I$. The value (k) is obtained by dividing the time of all high-load periods by the total time. The resultant actual rms current (i) can now be found from formula 2 or figure 4. From here on we have to distinguish between different classes of applications.

Class 1A: If with a load as shown in figure 3 or 10A the ventilation is essentially constant and the load periods short, find i/I. Then select from such tables as table II the nominal short-time rating for the current I which has a value S_1 at least equal to i/I.

Class 2A: If, again, with the load as shown in figure 3 or 10A the ventilation is essentially constant but the periods for some of the heavier loads are long, find S_2 from figure 7; determine i/S_2I, and select a rating having a value (S_1) which is at least equal to i/S_2I.

Class 1B: If the ventilation changes between heavy- and light- or no-load periods and the load periods are short (figure 3a or 10B), find S_3 from formula 7 or figure 9, determine i/S_3I, and select a rating at least equal to i/S_3I.

Class 2B: If the ventilation changes between heavy- and light- or no-load periods and some of the periods for the heavier loads are long, find both S_2 and S_3, determine i/S_2S_3I, and select a rating with S_1 at least equal to i/S_2S_3I.

If the load cycles are distributed rather unevenly in time as in figure 10C, it is evident that there will be some fluctuation in the temperature rise even though the individual load cycles are very short. If the periods (P) over which the load cycles are distributed are shorter than the rating time of the device, the use of a service factor of the general order of S_2 will give reasonably correct results. If, on the other hand, the period (P) is rather long as shown in figure 10D, it is safer to calculate results under the assumption that the load conditions prevailing during (P) are continuous. The loads in figures 10A to 10D have all been assumed to have the same value (I) and thus the same nominal current rating. It will be interesting to note the rms values of i/I and S_1 in figure 10 and the time values to be

Atmospheric Variations and Apparatus Flashover

P. H. McAULEY
ASSOCIATE AIEE

I. Introduction

IN practically all electrical apparatus use is made of the insulating properties of air. The electrical breakdown strength of air, for the electrode arrangements found in apparatus, depends upon air temperature, pressure and moisture content. This condition has long been appreciated and recognized in various standards for testing and for determining insulation ratings. However, the range and significance of the extreme conditions encountered, is not always appreciated. It is proposed, therefore, to consider the variations found in actual service and determine how well current standards and application practices cover these variations. In addition, the desirability of uniform application practices and reference ranges for different apparatus is suggested.

II. Current Practice

Wherever test margins are important, test values obtained under various actual weather conditions are corrected to the American standard conditions, which are:

Temperature	77 degrees Fahrenheit
Barometric pressure	29.92 inches of mercury
Humidity	0.6085 inches of mercury

According to most apparatus standards, equipment which meets the specified voltage tests, corrected to these conditions, may be used at any of the temperature and humidity conditions encountered in nature and at any barometric pressure encountered at altitudes up to 3,300 feet. The corrections for different air conditions are in many cases quite large and the actual flashover voltage of a piece of equipment in service may differ by as much as 25 per cent from the value for standard test conditions. The internal insulation of apparatus is not affected by the changing dielectric strength of the ambient air and in some cases the internal insulation may not be applied effectively and economically because of this situation. On the other hand, the internal insulation may be overstressed when conditions of unusually high external flashover prevail. Thus the variations in air conditions also are of some concern to the designer in that equipment insulation must be suitable for the most unfavorable conditions encountered in use.

III. Temperature, Pressure, Humidity

(*a*). TEMPERATURE

Flashover (and sparkover) voltages through air vary inversely with the absolute temperature. Figure 1 shows the variation in per cent for temperature ranges encountered in the U.S.A.

(*b*). BAROMETRIC PRESSURE

Flashover voltages vary directly with the barometric pressure. In a given location the pressure ordinarily does not vary through more than a five per cent range. However, barometric pressure and the dielectric strength of air do vary with altitude. Figure 2 indicates the relation.

(*c*). HUMIDITY

Flashover voltages for nonhomogeneous dielectric fields vary with the absolute humidity of the air. The change in these voltages depends upon wave form, polarity, and the kind of apparatus tested. Correction curves, of which figure 3 is typical, must be obtained experimentally.

(*d*). RELATIVE AIR DENSITY

The effect of temperature and of pressure have been combined into a single

---

chosen for the ratings; the latter range from 15 to 60 minutes for the various service conditions.

(b). AUXILIARY DEVICES AND CONDUCTORS

For all classes of applications discussed under "main devices," safe temperature rises are obtained for the auxiliary devices and conductors if they are rated for the same current value (I) and the same time as the main apparatus, assuming that the method of establishing short-time ratings outlined under class $2A$ is followed. For applications $1A$ and $1B$ with short-load periods which are definitely limited by the type of application, further economies can be safely effected by selecting auxiliary devices and conductors having continuous ratings corresponding to the actual rms values, as discussed under $1A$ and $1B$.

Obviously, all the methods outlined here may have to be modified in extreme or unusual cases which depart from the assumptions and limitations indicated in the paper.

Conclusions

The selection of the most suitable and economical short-time ratings of main devices, auxiliary devices, and conductors, all properly co-ordinated, has been reduced to an extremely simple procedure for many of the intermittent and varying loads found in practice. Uncertainties and uneconomical combinations previously encountered can be eliminated by the co-ordinated practices suggested for rating and application.

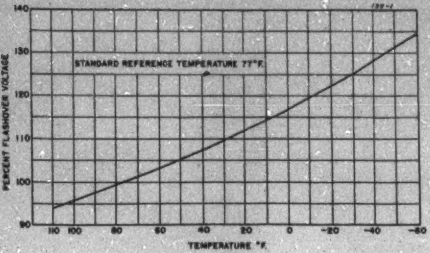

Figure 1. Flashover voltages vary through a range of over 30 per cent due to temperature changes of ambient air

factor, known as relative air density, which is unity for the standard conditions of temperature and pressure. For other conditions the relative air density is

$$\frac{17.95\times\text{bar. press. (inches)}}{460+\text{temp. degrees Fahrenheit}}$$

Flashover voltages actually vary at a rate less than the relative air density, but for practical purposes, the slightly pessimistic assumption that they follow the relative air density directly is satisfactory.[1]

(*e*). Magnitude of Changes

It is seen that temperature alone may produce a change in flashover voltage of 30 per cent. An elevation of 3,300 feet reduces flashover voltage 11 per cent, neglecting daily variations. Annual variations in humidity cause a change in flashover through a 20 per cent range. These effects, therefore are important and their combined results are of interest.

IV. Service Conditions

(*a*). Temperature

Temperatures in the continental U. S. vary from 120 degrees Fahrenheit to −50 degrees Fahrenheit. In terms of the variation from 100 per cent flashover at 77 degrees Fahrenheit, these correspond to −8 per cent and +31 per cent change. Maximum and minimum temperatures for some typical cities, where high voltage apparatus may be used, are given in table I.

(*b*). Barometric Pressure

An altitude map of the U.S.A. is shown in figure 4. Maximum and minimum altitudes by states are given in table II. It follows that a considerable part of the western states is above the 3,300-foot level to which standard apparatus is applicable. From table I also, the elevations of the cities listed range up to 7,000 feet. Consequently, a good deal of equipment is installed at altitudes above the standard range of 3,300 feet.

(*c*). Humidity

In general, the absolute humidity is lowest at low temperatures, where the air becomes saturated at very low moisture contents. For locations near large bodies of water high temperatures and high humidities tend to coincide and these two factors tend to cancel in their effect on flashover. However, table I indicates that, for the high inland locations, absolute humidities are quite low, even at times of maximum temperature, at Denver, for example.

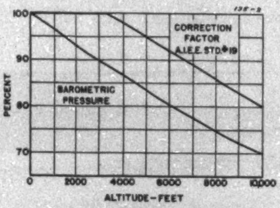

Figure 2. Flashover voltages vary directly with the barometric pressure which is 70 per cent of mean sea level pressure at 10,000 feet altitude

(*d*). Combined Effects

The change in flashover voltages for these extreme conditions in certain cities has been calculated and is shown in table III. The range of the variations likely to be encountered in extreme cases is around 27 per cent. Attention is called, however, to Great Falls, Montana, which is just below the 3,300-foot altitude limit. At this location, standard apparatus would at times suffer a reduction in flashover strength of practically 25 per cent. It should be pointed out that variations in barometric pressure and in humidity from the values assumed or recorded might influence the figures given another two or three per cent in either direction.

V. Rain, Fog, Dirt, Salt Spray

In addition to encountering a reduction in the dielectric strength of air, electrical insulating surfaces, such as porcelain bushings and insulators, frequently are subjected to rain, fog, and foreign deposits. A heavy rain will reduce the flashover voltage of a new clean insulator 30 per cent. Fog or rain on a dirty insulator may reduce the effectiveness of the insulator to the point where operation at rated voltage is impaired. In such cases special types of insulation may be applied or periodic cleaning may be found necessary. Wanger[2] and others have presented quantitative data on this subject, which is outside the scope of this paper.

VI. Apparatus

For a practical illustration of apparatus application, bushings will be considered. The basic insulation levels, based on an impulse voltage-withstand test, for different voltage classes have been suggested for standardization.[3] These levels are shown in figure 5, with the reduced corresponding values for altitudes of 5,000 and 10,000 feet. For the higher voltage classes, the next higher voltage class applies quite well for steps in elevation of the order of 3,000 to 5,000 feet. From 15 to 69 kv the insulation steps do not lend themselves as readily to this practice. Naturally, in any practical application compromises must be made between maintenance of insulation levels and subjecting internal insulation of apparatus to excessive voltages. To avoid an excessive number of designs, it probably is

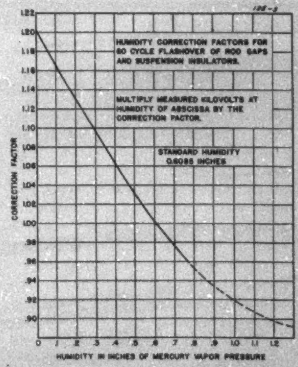

Figure 3. Flashover voltages vary with absolute humidity. The annual range is over 20 per cent for locations at moderate altitudes

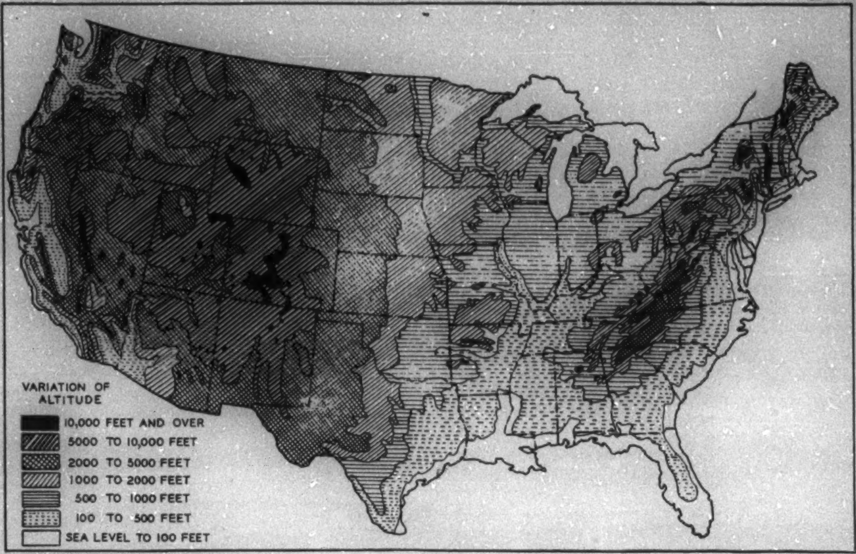

Figure 4. The mean elevation of the United States, including Alaska, is 2,500 feet. About 8.3 per cent of the earth's land lies above 6,000 feet and about 2.5 per cent is above 12,000 feet elevation

most economical to use the next largest bushing with a gap to reduce its flashover at the altitude in question to the basic insulation level of the apparatus. The variations due to temperature and humidity cannot be controlled. Hence, excessive approximations in apparatus application for a given altitude are to be avoided.

Figure 6 shows the effect of altitude on the flashover of 34.5- and 115-kv bushings. The relative flashovers of the next higher voltage steps in 3,300-foot ranges also are indicated. For the 115-kv case, the maximum spread from the basic level using the next higher class of standard bushings is seven per cent. This is likely to be further decreased in practice on account of the lower humidities encountered at higher altitudes. In general, the relative flashover levels lead to a fortunate situation. This is not the case for the 34.5-kv class. The spread between the 46- and 69-kv classes is too great for application in the simple manner found above. For this reason, it has been the practice to use "high-altitude" bushings of appropriate flashover in this range.

VII. Testing Margins

Since apparatus is now tested on a withstand voltage basis, all equipment has a small margin over the basic levels to avoid troubles in acceptance tests. These margins, of course, raise the actual flashover range in terms of voltage. However, although the mean flashover is thereby raised, the width of the band due to atmospheric variations remains the same. The net result is that the internal insulation may be worked a little harder in actual service.

VIII. Upper Air Investigations

A subject of increasing interest is the weather conditions at high altitudes above the ground. Figure 7 gives some early data[7] on this point. Temperature pressure and humidity decrease with altitude, of course. However, the very rapid decrease in absolute humidity and the low moisture content at an altitude of 20,000 feet even with a high value at sea level are very striking.

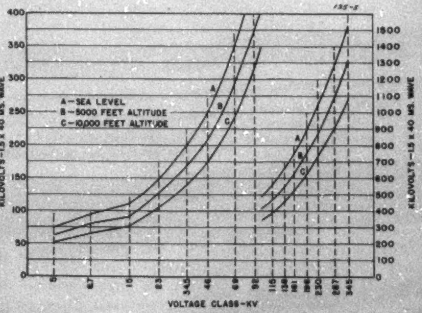

Figure 5. The impulse-withstand voltage ratings of bushings are affected as shown at the 5,000- and 10,000-foot levels

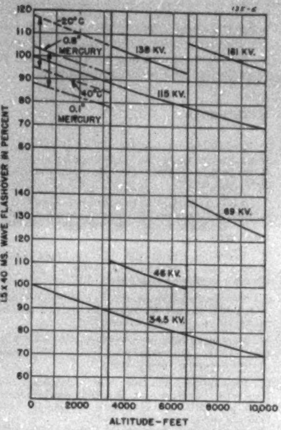

Figure 6. The relation of adjacent voltage classes of apparatus permits applying the next higher classes for different altitude ranges in the higher voltage cases and not in the lower operating voltage classes

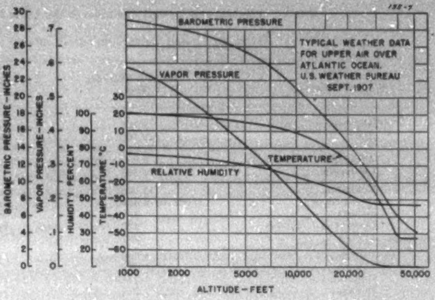
Figure 7. Upper air investigations give the variations in weather conditions with altitude. Conditions change of course, with geographical location and with the seasons and time of day



IX. Apparatus Standards

As already stated, apparatus standards permit apparatus of standard voltage rating for elevations up to 3,300 feet. AIEE Standard No. 19 for oil circuit breakers states, "for application at altitudes greater than 3,300 feet, it is recommended that the standard voltage rating of the apparatus should be multiplied by the following factors to obtain the modified voltage rating."

Altitude in Feet	Correction Factor
3,300	1.00
4,000	0.98
5,000	0.95
10,000	0.80

These recommended corrections are shown in figure 2 and their actual relation to the decreasing barometric pressure can be seen. There are a few exceptions to the 3,300-foot standard range, based on thermal rather than flashover limitations. Railway motors, AIEE Standard No. 11, may be used through a range up to 4,000 feet. NEMA Industrial Control Standard gives a range of 6,000 feet and a derating factor for the 6,000–15,000-foot range. These are practical figures based on much experience which help to simplify application problems. However, the adoption of a multitude of ranges as a result of selecting the optimum for each type of apparatus is not to be recommended.

X. Conclusions

1. Temperature changes of the ambient air in the U.S.A. change the flashover voltage of apparatus through a range of 39 per cent.
2. An elevation of 10,000 feet reduces flashover voltages 30 per cent from those at sea level.
3. Variations in absolute humidity result in changes in flashover voltage of nearly 20 per cent.
4. In any one location the combined ef-

Wisconsin	1,940	582
Wyoming	13,785	3,100

fects of these variables is not likely to exceed a 25 per cent range.

5. Standard apparatus applied at different locations in the range of elevations up to 3,300 feet will vary in flashover over a possible range of 35 per cent.

6. For many applications standard apparatus of the next higher voltage class fits the mean flashover range of the location.

7. For other cases it is necessary to use special apparatus or to gap equipment of excessively high rating to meet the average flashover requirements for the conditions encountered at a given location.

8. The desire to maintain flashover values and to avoid overstressing internal insulation prescribes permitting wide departures from basic insulation levels due to conditions of application.

9. This survey would seem to show greater variations in flashover voltages due to changing weather conditions in service than is generally realized. Although the situation is not to be regarded as alarming, it is well to keep it in mind. A full appreciation of the facts in a particular case should lead to a more effective application of apparatus to meet the conditions. On the other hand, certain applications which may have proved unsatisfactory might be explained by these simple natural phenomena. In addition, standardizing groups often find it necessary to consider information of this nature in formulating and revising standards.

Appendix

Altitude Corrections

The effect of altitude on apparatus rating is given in at least four different forms in the AIEE and ASA standards. Altitude affects voltage rating (flashover through air), cooling (air density) and losses (windage). More uniformity of terminology and method of specification appears possible and desirable.

In Standard No. 19 correction factors for voltage rating are given in the form of a table as given in section IX of this paper. The table values correspond exactly to one per cent reduction for each 330 feet above 3,300-feet altitude. In the same standard the correction for temperature rise is given as 0.4 per cent reduction for each 330 feet above 3,300 feet at which the actual installation is to take place.

In ASA Standard *C*-50 for rotating electrical machinery, the probable decrease in

Volt-Time Areas of Impulse Spark-Over

J. H. HAGENGUTH
ASSOCIATE AIEE

Synopsis: On the basis of classification of impulse wave shape, the paper shows that impulse spark-over characteristics of electrodes with nonuniform fields cannot be represented by single volt-time curves but must be represented by volt-time areas of considerable extent. This classification explains the large difference obtained by various laboratories when investigating sparkover between one and five microseconds. The effect of impulse generator discharge circuits in producing these differences is explained. The necessity of insulation co-ordination on the basis of volt-time areas is pointed out.

Introduction

EVER since it was definitely established that lightning strokes contribute the greatest amount of insulator flashovers on transmission lines as well as damage to important equipment such as transformers and circuit breakers, the problem of insulation co-ordination on the basis of impulse sparkover has become of great concern to the operating engineer, not only as a means of eliminating damage, but also of preventing flashovers causing system outages. Many papers[1] have been written on the large problem of co-ordination.

Co-ordination has been defined in various ways. One of the more recent definitions[2] is as follows:

> 'Insulation co-ordination may be defined as the process of setting standards of insulation strength and assigning them to all the items of equipment in the various insulation classes in such a manner as to produce, from an economic and operating standpoint, both a maximum of protection, and, if failure results, a minimum damage to the system."

From this definition it is apparent that the impulse strength of all types of apparatus comprising a transmission system has to be known, within fairly accurate limits, before co-ordination can be applied effectively. Consequent studies of the impulse flashover characteristics of suspension insulators, apparatus insulators, bushings as well as transformer insulation revealed that the impulse flashover in air, oil, or breakdown of solid insulation is not a constant value, but varies with time. Therefore, impulse strength of a given electrode arrangement and dielectric can be represented by a volt-time curve which correlates the spark-over voltage with the time at which the insulator will spark over.

Present Concept of Impulse Spark-Over Characteristics

In figure 1 a series of such volt-time curves are shown for different types of electrodes. The curves are plotted as overvoltage-time curves to show the relative increase of spark-over voltage as affected by the electrode arrangement. Overvoltage is the actual spark-over voltage expressed in per cent of the critical[*] spark-over voltage of the apparatus.

It is evident from a study of these curves that co-ordination on the basis of the critical spark-over voltage of different types of apparatus only cannot be effective, but that co-ordination must be based on the volt-time impulse characteristics of the apparatus. While the various laboratories in the United States of America conducting high-voltage research did agree within fairly close limits on the critical spark-over voltages of rod gaps and insulators,[3] considerable differences in results were obtained for volt-time spark-over curves.[4,5] For instance, the differences in measured spark-over voltages for rod gaps were found to be as great as 20 to 40 per cent at times to sparkover of two microseconds and less. These large differences were at first attributed to measuring methods such as the type of divider—resistance divider, shielded and unshielded, and capacitance divider—as well as insufficient precaution in the oscillograph technique. However, it was soon discovered that the shape of the applied impulse wave before sparkover occurs has a distinct bearing on the spark-over voltage of different types of apparatus.[6] The effect of wave shape,

Paper 41-75, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted November 27, 1940; made available for preprinting December 26, 1940.

J. H. HAGENGUTH is an electrical engineer for General Electric Company, Pittsfield, Mass.

The author wishes to acknowledge the assistance of A. F. Rohlfs in the preparation of the paper and of G. G. Poulsen and J. W. Albright in obtaining the test data.

1. For all numbered references, see list at end of paper.

[*] The critical spark-over voltage of a test specimen under an impulse of any given wave shape and polarity is the crest value of that impulse when its amplitude is adjusted to cause flashover on 50 per cent of the applications.

---

ambient temperature at higher altitudes is recognized and applications at normal rating approved if the operating conditions are within the limits given in the following table.

Altitude In Feet	Altitude In Meters	Maximum Temperature of the Cooling Air in Degrees Centigrade
0– 3,300	0–1,000	40
3,300– 6,600	1,000–2,000	35
6,600– 9,900	2,000–3,000	30
9,900–13,200	3,000–4,000	25

In this case the percentage change varies with the different values of temperature rise since corrections are given in degrees of temperature.

In standard *C*-50 also, a correction of one per cent per 330 feet above 3,300 feet is specified for temperature-rise tests at low altitude on apparatus destined for use at altitudes above 3,300 feet.

ASA standard *C*-57 for transformers, regulators, and reactors gives corrections for temperature rise in per cent per 330 feet above 3,300 feet. Rates from 0.4 to 1 per cent are given depending on whether cooling is largely by radiation or conduction.

AIEE Standard No. 4 for voltage measurement gives a correction for spark-over voltages in air which includes both temperature and pressure (altitude) factors. Measured voltage values are divided by the relative air density to correct to standard conditions.

$$\text{relative air density} = \frac{0.392B}{273+T}$$

where

T = temperature degrees centigrade
B = pressure in millimeters of mercury

ASA standard *C*-50 gives a correction formula for windage losses for different temperature and pressure (altitude) conditions. The losses measured at a given temperature and pressure are multiplied by the factor $690\,\frac{(1+0.004T)}{B}$, in which T = temperature degrees centigrade and B = pressure in millimeters of mercury. Both this and the relative air density formula are unity at 25-degrees-centigrade and 760-millimeter pressure and one is the reciprocal of the other for practical purposes.

The International Electrotechnical Commission proposed specification for a-c circuit breakers (May 1938) states that the limits of temperature rise shall be reduced one per cent for each 300 meters (990 feet) above sea level at which the breaker is intended to work in service. The correction is not applied below 1,000 meters. In this case both the rate and the starting point of the correction are different from American Standards.

however, could not be classified, and, therefore, useful engineering data could not be supplied. Owing to the differences obtained by various laboratories, the volt-time curves were assigned plus and minus corrections of arbitrary value to account for what was thought to be erratic spark-over characteristic of certain types of apparatus.

New Concept of Impulse Spark-Over Characteristics

It will be left to the physicist to translate the following data into electrons, ions, and terms of photo-ionization. This paper will attempt to present the data in terms which the engineer interested in co-ordination and, therefore, in impulse spark-over characteristics of different kinds of apparatus, can use to apply to his problems.

The effect of wave shape is well illustrated by figure 2 which shows a series of volt-time curves and spark-over points for a 20-inch rod gap at negative polarity. Each of these curves was obtained with a constant impulse generator discharge circuit. For the lower curve the impulse wave had a front of 0.5 microseconds, for the middle curve a front of 2.4 microseconds and for the upper curve, 9.6 microseconds at the critical spark-over potential. It can be seen that the spark-over voltages associated with a given time to sparkover vary greatly with the shape of the wave front. For instance, at two microseconds the spark-over voltages for the two extreme wave fronts used are 495 kv and 625 kv respectively with a difference of 25 per cent. If, at the same time to sparkover, widely differing voltage values are obtained, gap spark-over has to be classified as either very erratic or the difference must be due to some physical characteristics of the spark-over phenomenon. If spark-over voltages at two microseconds of 495 kv and 625 kv of a 20-inch rod gap had been obtained in isolated tests and not in the course of obtaining volt-time curves, the spark-over characteristic of the gap would indeed appear erratic.

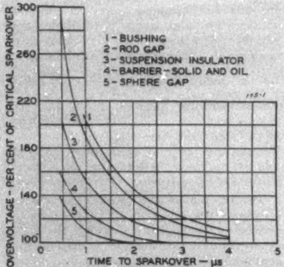

Figure 1. Comparison of overvoltage characteristics of different types of gaps

Negative polarity

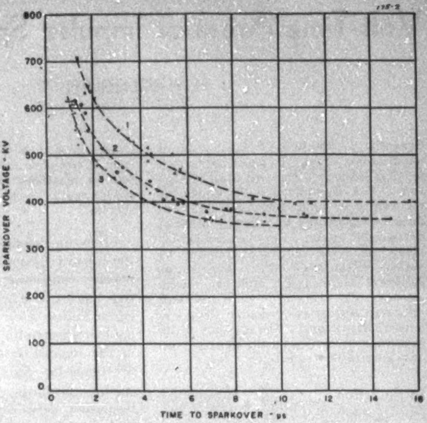

Figure 2. Effect of wave front on spark-over volt-time curves for a 20-inch rod gap

Negative polarity. Vapor pressure 0.26 inch mercury; air density 0.983

Impulse circuit adjusted for: 1—9.6-microsecond wave front, 2—2.4-microsecond wave front, 3—0.5-microsecond wave front

However, since the results shown in figure 2 were obtained with impulse waves of different shapes, it is logical to attribute the difference to wave shape. Since the front of the wave definitely appears to have considerable influence on the variations in spark-over voltage, but, on the other hand, the front of the wave does not stay constant when sparkover occurs between two and ten microseconds, it was decided that the effective front might be used to derive a practical answer for classification of impulse wave shape. The effective front is specified by the slope of the line through the $0.3E$ and $0.9E$ points on the front, where E is the crest of the measured wave. The effective front in microseconds T_1 is the time between the $0.3E$ and $0.9E$ points multiplied by 1.66. For the tests with the slow front, this definition of effective front did not permit sufficient differentiation. Since slow fronts in all cases were of the exponential form, the initial rate of rise was used as the effective front. The time to sparkover T_2 in microseconds is the time from virtual zero time to a point on the wave where voltage is rapidly decreasing toward zero. Virtual zero time is defined as the intersection of the line through the $0.3E$ and $0.9E$ points with the zero line.

The same test points as shown in figure 2 were then replotted as function of kilovolt spark-over and the ratio of T_1/T_2 = (effective front)/(time to sparkover) with time to sparkover T_2 as parameter. Such a plot shows a scattering of points, indicating the trend of lower spark-over voltage for small ratios of T_1/T_2 and higher spark-over voltages for large ratios of T_1/T_2 for equal times to sparkover. In figure 3 the test points were plotted to show the range over which data have been obtained, but the time to

sparkover associated with each test point was omitted for reasons of reproduction. The network of straight lines, indicating spark-over voltage trends for a given time to sparkover, has been placed such that it most nearly represents the correct interpretation of the test results.

The lower limit $T_1/T_2=0$ and the upper limit $T_1/T_2=1$ have not been reached during these tests. The lower limit, of course, represents a wave with abrupt rising front and practically rectangular tail, while the upper limit represents a front rising in a straight line from the zero point to the spark-over point. Both of these limits are difficult to obtain in practical impulse testing. However, the error in extending the straight lines to both of these limits beyond the available test points should not result in appreciable errors.

To reduce the results to the customary form of the volt-time curves, the straight lines of figure 3 have been used to draw the curves of figure 4, where spark-over voltage in kilovolts is plotted as function of time to sparkover with the ratio T_1/T_2 as parameter.

This figure shows clearly that sparkover of a rod gap for instance cannot be represented by a single "volt-time curve" but rather by a "volt-time area." This volt-time area, in contrast to previous attempts of using correcting factors in connection with volt-time curves, is well defined by recognition of the influence of impulse wave shape on spark-over voltage. It will be shown that the use of the wave shape definition adopted gives results within a few per cent of expected spark-over voltages. Therefore, the use of volt-time areas will eliminate to a large extent the uncertainty heretofore associated with short-time sparkover of insulators, bushings, rod gaps, and other apparatus. It is important to note that this spark-over area, of course, is subject to the variations in spark-over voltage due to humidity and air density. The correct method of correcting for humidity throughout this spark-over area is not known. If the method at present used for volt-time curves is adopted[7] it means that at short times to sparkover the spark-over values will remain practically the same while at the longer times the spark-over voltages will be raised, so that the individual volt-time curves for different T_1/T_2 = constant will have a reduced slope at the longer times to sparkover, and the total spark-over area will be reduced when based on standard conditions of humidity. The air density correction probably will be the same regardless of wave shape.

It has been shown that the impulse spark-over voltage (e) of an electrode arrangement producing a nonuniform field, such as the rod gap, is a function not only of the time at which sparkover occurs, but also of wave shape represented by the ratio of T_1/T_2. Therefore $e=f(T_2, T_1/T_2)$. The physical condition for this dependence of spark-over voltage on wave shape is primarily the fact that corona currents of considerable amplitude have to flow through the dielectric to obtain sufficient ionization before sparkover can be completed.[8] The amplitude of these corona currents in turn depends on the voltage applied to the gap and the length of time voltage has been applied to the electrodes. Obviously wave shape cannot accurately be described by a ratio of T_1/T_2, especially for waves with unusual shapes, but in the range below six microseconds the results obtained indicate a sufficient consistency to justify the use of this approximation until more exact methods are available.

Volt-Time Areas of Different Types of Electrodes

The Quasi-Uniform Field

From the foregoing discussion it should be expected that spark-over voltage of electrode arrangements producing a uniform field should be represented by straight lines parallel to the zero axis (each spacing between electrodes represented by one line) and without the tendency of spark-over areas because heavy corona currents are not required to initiate sparkover. The closest approximation to the uniform field available for testing at higher voltages is the sphere gap at spacings small with respect to the diame-

ter of the sphere. The same types of waves used for the rod gap were applied to a 50-centimeter sphere gap spaced 15.5 centimeters. This spacing was chosen because it required a spark-over voltage approximately equal to the critical spark-over of the 20-inch rod gap.

The results of these tests are shown in figure 5. This figure shows in a greatly enlarged scale the test points and the probable volt-time curves for the three test conditions as outlined for the 20-inch rod gap. Only two test points were obtained for the short front-long tail wave. The differences between the two slow front waves are insignificant. At one microsecond the difference between minimum and maximum measured voltages is only nine per cent. Since the probable measuring error is of the order of three per cent, it can be said that the volt-time area of a sphere gap, representing a nearly uniform field is extremely small as compared to that of a rod gap at times to sparkover of one microsecond and greater. The data do not permit drawing of T_1/T_2=constant curves as shown for the 20-inch rod gap in figure 4.

The Nonuniform Field

In addition to the 20-inch rod gap at negative polarity, volt-time areas have been obtained for the 50-inch rod gap at negative polarity, figure 6, and the 20-inch rod gap at positive polarity, figure 7. In the latter two figures the test points have been superimposed on the plot of the T_1/T_2=constant curves as follows: The spark-over potentials in kilovolts as function of time to sparkover are represented by the solid points. From these test points an arrow is drawn to the expected location of the point according to the ratio T_1/T_2 of the wave. It is apparent that the test points check the expected values very closely. In figure 6 is also shown a conventional volt-time curve for the 50-inch rod gap taken with a 1.5x40 wave. It is evident that such a curve cannot represent the spark-over characteristics of the rod gap. Data of figure 6 and figure 7 have been corrected to standard conditions of humidity and air density according to accepted methods.[7]

Further tests have been made on a string of three suspension insulators (figure 8), a stack of two apparatus insulators (figure 9), and a bushing (figure 10). Only the T_1/T_2=constant curves for these different insulating elements have been plotted to indicate the slope of the curves and the extent of the volt-time areas for comparison with the other electrode arrangements investigated.

A comparison of the volt-time characteristics of the electrode arrangements of approximately equal critical spark-over voltages shows that the slope of the T_1/T_2=constant curves is steepest for the bushing, rod gap, line and apparatus insulators in the order named, while the extent of the spark-over areas is greatest for the rod gap, line insulators, bushing and pedestal insulators in the order named. This sequence corresponds well to the trend indicated by the single volt-time curves of figure 1. The electrode arrangement with the least overvoltage—the sphere gap—has the smallest volt-time area, while the higher overvoltages at a given time to sparkover of the single volt-time curve are indicative of larger volt-time areas.

The effect of wave shape on breakdown characteristics of barriers (representing major insulation of oil-filled transformers)—represented by overvoltage-time curve 4, figure 1—has not been investigated. Judging from this volt-time characteristic, the volt-time breakdown area of such a barrier should be intermediate between the spark-over areas of the sphere

Figure 7. Spark-over volt-time area of 20-inch rod gap

gap and the line insulators, depending greatly on the type of electrodes and the field between them. Further tests are needed to obtain data comparable to those represented in the paper for air dielectrics.

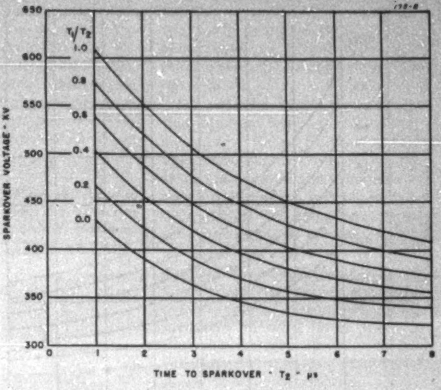

Figure 8. Spark-over volt-time area of a three-unit string of suspension insulators

T_1 = effective wave front; T_2 = time to spark-over

It has been customary[9,10] to represent rod gap spark-over voltages as function of rod gap spacing with the time to sparkover as parameter; similarly, insulator sparkover is represented as function of number of insulators or string arc-over distance. Such curves were based on single volt-time curves taken at various spacings using a standard 1.5x40 wave. On the basis of spark-over volt-time areas, such curves should be drawn for each T_1/T_2 = constant curve, or, since the limiting conditions are of greatest importance, for the two conditions $T_1/T_2=0$ and $T_1/T_2=1$.

The results of the tests presented here permit the plot of such curves for the rod gap between 20-inch and 50-inch spacing at negative polarity (figure 11). To conserve space, curves for the two extremes have been plotted on the same figure and, to avoid overlapping of the extreme ranges, the curves shown range only between two microseconds and four microseconds to sparkover. In addition, typical curves as obtained with the 1.5x40 wave are included.

Effect of Impulse Generator Circuits on Spark-Over Voltage

It is interesting to note that the solid two-microsecond curve as obtained from tests with a 1.5x40 wave (figure 11) is a curve rather than a straight line. This means, of course, that the wave shape at two microseconds to sparkover of the 20-inch rod gap was different from the wave shape during tests on the 50-inch rod gap, although the wave shape at the longer times to sparkover was practically the same in both tests as indicated by the straight lines for three microseconds and four microseconds.

This difference in wave shape at the short times to sparkover is due to the effect of the corona currents required for ionization of the gap to complete spark-over and the resulting voltage drop in the series impedance—inductance and resistance—of the impulse generator discharge circuit. The resulting change of the wave shapes is shown in figure 12. On this figure the wave shape at two microseconds to sparkover is compared with the wave shape at critical sparkover for two types of impulse generator discharge circuits. In figure 12*a* the wave shape is controlled by a series resistance and a small load capacitance which principally consists of the inherent capacitance of the impulse generator plus a small additional load capacitance, a total of approximately 300 micromicrofarads. In order to obtain a 1.5-microsecond front with such a small capacitance, it is necessary to use a series resistance of 1,700 ohms. The corona currents through the gap have an amplitude of the order of hundreds of amperes and, therefore, the voltage drop through the resistor is several hundred thousands of volts. This voltage drop subtracts from the wave as it would have appeared, if the corona currents had not flown through the gap. The effective wave front is, therefore, changed from a 1.2-microsecond front at critical sparkover to 0.6 microsecond at 2 microseconds to sparkover. Therefore, the ratio of T_1/T_2 for this wave at two microseconds is $0.6/2=0.3$ which results in a spark-over voltage of 534 kv from figure 4 when corrected for air conditions. This checks the value of 535 kv obtained from figure 11.

In the other circuit, figure 12*b*, the load capacitance is concentrated close to the rod gap and has a value of 800 micromicrofarads. The series resistance is 800 ohms giving a front of 1.8 microseconds and an effective front of 1.3 microseconds. For equal amounts of corona currents, as for the circuit 12*a*, the voltage drop across the resistor due to the corona is considerably reduced because it can be supplied by the capacitor direct without any appreciable voltage drop. Consequently, the effective front is not changed and at two microseconds to sparkover the ratio $T_1/T_2=1.3/2=0.65$. From figure 4 a spark-over voltage of 587 kv results, which, when corrected to standard conditions of humidity and air density, gives 610 kv as compared to 534 kv obtained with impulse generator circuit of figure 12*a*. This spark-over voltage of 610 kv was actually obtained during tests on the 20-inch rod gap with circuit of figure 12*b* in the process of obtaining a volt-time curve before and independent of this present investigation. Data of figure 4 have been obtained recently. It is, therefore, significant to the value of this proposed classification of impulse wave shapes in terms of T_1/T_2 that test data on the same type of gap taken several years ago should check so well when analyzed on the basis of that ratio.

The solid curves shown in figure 11 were obtained with an impulse generator connected as in figure 12*a* for the 20-inch and 30-inch gap, while the tests for the 50-inch gap were made with circuit of figure 12*b*. If the value of 610 kv for the 20-inch rod gap is plotted on figure 11, a straight line for the two-microsecond test curve results.

These examples show that

1. Differences in spark-over voltages obtained on electrode arrangements with non-uniform field are directly due to differences in impulse generator discharge circuits.

2. Spark-over voltages, when classified according to wave shape as expressed by the ratio of effective front to time to sparkover, are consistent on the basis of spark-over volt-time areas, although they appear erratic on the basis of volt-time curves.

3. The effective wave front produced by some types of impulse generator discharge circuits during investigations of impulse volt-time curves of apparatus with non-uniform field varies considerably throughout the range of times to sparkover from critical to one to two microseconds. Such generators produce volt-time curves where neither T_1 = constant nor T_1/T_2 = constant. The change in effective front depends on the type of apparatus tested, whether large or

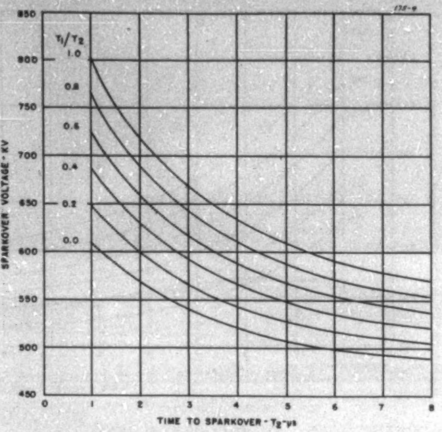

Figure 9. Spark-over volt-time area of a two-unit stack of apparatus insulators

T_1 = effective wave front; T_2 = time to spark-over

small corona currents are required to complete sparkover.

4. The effective wave front produced by the other type of generator is constant throughout the same range of time to sparkover. Therefore, the volt-time curve produced has a constant T_1. Wave shape at any given time to sparkover is practically independent of the type of apparatus tested. It is, therefore, clear that for purposes of comparison of volt-time curves of apparatus with great differences in electric field distribution, tests made with an impulse generator discharge circuit of the type shown in figure 12*b* are directly comparable. Similar tests made with a generator of the type shown in figure 12*a*, however, are not directly comparable and have to be interpreted with considerable care. Until volt-time areas of all types of insulation structures are available, the effective fronts obtained during tests on volt-time curves should be recorded throughout the range investigated, since they have such a profound effect on the values of spark-over voltages obtained.

Effect of Volt-Time Areas on Co-ordination

The data are obtained on too few types of apparatus to enable complete understanding of all the requirements for effective co-ordination. However, sufficient data are presented to make general recommendations. For this purpose the term co-ordination is used in a restricted sense, such that "co-ordination between two apparatus is obtained if the impulse strength of one of them is below the other, so that sparkover always occurs on the apparatus with lower strength." On the basis of volt-time curves this means that the volt-time curve of apparatus *A* is lower than that of apparatus *B* throughout the expected spark-over time range.

As shown by the examples of the sphere gap and the insulators, quasi-uniform fields between electrodes are associated with small impulse spark-over areas, while the nonuniform field is associated with large impulse spark-over areas. The problems of co-ordinating voltage levels for the large variety of electrode fields encountered in electrical apparatus, therefore, consists in co-ordinating according to spark-over areas rather than according to single volt-time curves. This, of course, complicates the co-ordinating problem to a certain extent.

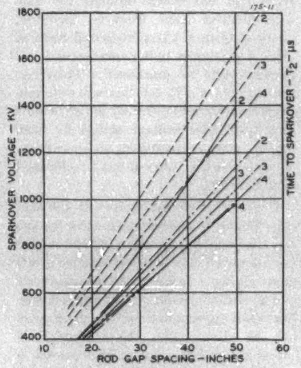

Figure 11. Impulse spark-over characteristics of rod gaps

Negative polarity. Standard conditions of humidity and air density

Solid lines—tests with 1.5x40 wave
Dashed lines—$T_1/T_2=1$ curves
Dot-dash lines—$T_1/T_2=0$ curves

T_1 = effective wave front; T_2 = time to spark-over

However, the problem can be reduced to three fundamental conditions (figure 13):

(*a*). Apparatus with the lower impulse strength (*A*) has a narrow band spark-over area; apparatus with the higher impulse strength (*B*) has a wide band spark-over area (for instance, a sphere gap (*A*) and insulator string (*B*)).

In this case co-ordination can be made effective if the $T_1/T_2=0$ spark-over curve of (*A*) is below the $T_1/T_2=0$ spark-over curve of (*B*) because regardless of wave shape, the impulse strength of (*A*) will be exceeded before that of (*B*) is reached.

(*b*). Apparatus with the lower impulse strength (*A*) has a wide band spark-over area; apparatus with the higher impulse strength (*B*) has a narrow band spark-over area. In this case, co-ordination can be made effective if the $T_1/T_2=1$ spark-over curve of (*A*) is below the $T_1/T_2=1$ spark-over curve of (*B*).

(c). Regardless of the band of the spark-over areas of both apparatus co-ordination is effected if the $T_1/T_2=1$ spark-over curve of (A) is below $T_1/T_2=0$ spark-over curve of (B).

Condition (c), of course, is the most satisfactory method of assuring that apparatus with the lower impulse strength will reduce the impulse voltage before the impulse strength of (B) is reached. However, under conditions where the margin between apparatus (A) and (B) can be kept to a minimum, matching of the spark-over areas as indicated in figure 13, (a) and (b) should give considerable improvement as compared to a consideration of single volt-time curves only. It is obvious that apparatus with nonuniform field and consequent wide band spark-over areas are not suited to limit impulse spark-over voltages in stations where costly equipment may be damaged if the limiting level of the apparatus is set too high. If, on the other hand, the limiting level is set sufficiently low, following condition of figure 13c, the spark-over characteristics will be such that switching surges and other low and medium system disturbances will result in a large number of system outages.

Wave Shape Variations on Transmission Lines

The question naturally arises whether apparatus in service will be subjected to waves of such a great variety of shapes as to warrant the investigation of impulse sparkover of areas as has been done in this paper for a few types. The available data are limited, due to the very costly nature of investigations of wave shapes of natural lightning on transmission lines, but approximate limits can be given.

Lewis and Foust[11] give a summary of a study of natural lightning on transmission lines in the United States of America which shows that wave fronts may vary between 1 microsecond and 80 microseconds wave tails between 4 and 160 microseconds. Berger[12] in Switzerland recorded wave fronts up to 80 microseconds causing flashover of insulation at a terminal station. From these limited measurements of traveling waves on actual transmission systems, the possibility of great variations in wave fronts and wave shapes is indicated. Therefore, the large variations in spark-over voltages, as shown to exist for electrode arrangements with nonuniform field, are a distinct possibility and should be taken into account in the co-ordination problem.

Conclusions

1. Impulse spark-over voltages of electrode arrangements with nonuniform field—such as insulators, bushings, rod gaps—cannot be represented with sufficient accuracy by volt-time curves, but must be represented by volt-time areas.

2. The extent of these areas may be considerable. The spark-over voltage of a string of three suspension insulators for instance, ranges between 430 kv and 620 kv with sparkover taking place at one microsecond, a difference of 45 per cent, or at six microseconds to sparkover the spark-over voltage ranges between 330 kv and 430 kv, a difference of 30 per cent.

3. The great differences in voltages at any given time to sparkover are not due to erratic nature of sparkover, but due to differences in the shape of the applied impulse wave before sparkover occurs.

4. The experimental data show that differences in wave shape can be classified by the ratio of the effective front of the wave to the time to sparkover—T_1/T_2. $T_1/T_2=0$ represents a wave with very steep front and practically rectangular tail while $T_1/T_2=1$ represents a wave with a front rising in a straight line from zero time to the time of

sparkover. Wave shapes where the ratio T_1/T_2 is small are associated with the lower spark-over voltages while straight line voltage rise produces the highest spark-over voltage at any given time to sparkover.

This means that the customary volt-time curves give only a very incomplete spark-over characteristic for any given electrode arrangement. The deviations from such curves are summarized in the following table (data from figure 6) for the 50-inch rod gap.

		Time to Spark-Over—Microseconds				
		2	3	4	5	6
Total spread of spark-over voltage in per cent of lower boundary		44	38	33	28	25
Per cent difference from typical volt-time curve with $T_1 = 1.3$ microseconds	+	13	19	21	21	22
	−	28	16	11	6	2

The maximum and minimum differences between the boundaries of the spark-over areas and volt-time curves depend on the impulse generator connection used for obtaining the curves.

5. The dependence of spark-over voltages on wave shape explains the great difference of spark-over voltage for a given electrode arrangement reported from different laboratories. The differences, in the range of one microsecond and more, are principally due to the difference in types of impulse generators used for the investigations. Although two impulse generators may produce the same wave shape at critical sparkover, at shorter times to sparkover (four microseconds and less) the wave shapes become radically different. One type produces a wave with a short effective front. Therefore, T_1/T_2 is small and the resulting spark-over voltage is low; the other produces a wave with a practically constant effective front. Therefore, T_1/T_2 is large and the resulting spark-over voltage is high.

Thus, this classification of wave shape is a satisfactory means for explaining the large voltage differences observed by various laboratories at times to sparkover of one microsecond or more.

6. The same phenomena which cause the upturn of spark-over volt-time curves are responsible for spark-over volt-time areas. Impulse sparkover in the nonuniform field requires corona currents of considerable amplitude to complete sparkover. The amplitude and the length of time of current flow determine the time to sparkover and the crest voltage of the wave causing sparkover. Therefore, for equal times to sparkover, a wave shape for which corona starting voltage is attained in a short time will require a lower spark-over voltage than a wave shape where corona starting voltage is attained later. Likewise, for equal spark-over voltages, early start of corona current will produce a shorter time to sparkover than a late start of corona currents.

7. Therefore, in the quasi-uniform field, such as the sphere gap, where corona currents are of small amplitude or negligible at times to sparkover of one microsecond or more, the effect of wave shape on the spark-over characteristic is very small, the upturn of the volt-time curves is negligible, and the extent of the spark-over area is negligible. At times shorter than one microsecond the effect of corona current becomes considerable and the sphere gap should exhibit increasing extent of spark-over area and upturn of voltage.

8. Methods of co-ordinating system insulation on the basis of impulse spark-over areas rather than volt-time curves are pointed out.

9. The data presented here are only another step to a more complete understanding of spark-over phenomena. The classification of impulse wave shape by means of a simple ratio of effective front to time to sparkover, while not based on a precise scientific interpretation of the phenomenon, nevertheless gives excellent practical results.

Effect of Sapphire-Crystal Orientation on the Wear of Watt-Hour-Meter Bearings

J. H. GOSS
ASSOCIATE AIEE

Synopsis: This paper describes the most recent of a series of studies on the life of watt-hour meter bearing materials. It covers an investigation of the effect of jewel crystalline axis orientation upon jewel wear.

Lifetime stability of meter calibration is a function of bearing wear. A study of the wear (after several years' service) of the sapphire jewel cups of meters in relation to crystalline orientation confirms predictions of another investigator; and a corroborative theory, based upon the physics of crystals, is presented.

Introduction

THE importance of the induction type watt-hour meter in the complex structure of the modern distribution system is fully realized. Accurate metering is necessary because the electrical characteristics and the initial and sustained accuracy of the watt-hour meter are directly reflected in terms of revenue produced. Much work has been done over a long period of years to improve the electrical characteristics and to perfect the mechanical parts. The lower bearing which carries the load of the moving system has long been given close study because it plays a real part in sustained meter accuracy.

It is the purpose of this article to describe briefly the results of work that has shown a marked correlation between the wear of the sapphire jewel cups used in the lower bearings and the direction with which the cups are cut with respect to the sapphire crystal structure. The wear of the jewel cups affects the useful life of the lower bearing and the sustained accuracy of the watt-hour meter.

For many years, it has been generally known that certain crystalline substances exhibit different hardnesses on various crystal faces. In 1931, V. Stott[1] working in the National Physical Laboratory experimented with the wear of sapphire watt-hour meter jewel cups cut at various known angles with respect to the major axis of the sapphire crystal.

In 1936 V. Stott released a further account of work done in the National Physical Laboratory in a special report.[2] This report gave the results on 156-watt-hour meter jewel cups cut in definite crystal directions. The report indicated quite conclusively that there was a definite relation between wear and crystal direction. The apparatus used in making these tests was described in the first paper[1] and while it was designed especially for the work, represented a laboratory test which gave different operating conditions than a bearing experiences in a watt-hour meter.

It is desirable at this point, in order to understand properly the meaning of the term, "orientation" which is used to designate the direction with which the sapphire cup is cut with respect to the crystal axes, to consider briefly the subject of crystals and crystal structure.

Crystal Structure

Sapphire is crystalline alumina, Al_2O_3 and is a form of the mineral corundum. It is crystalline in structure and belongs to the hexagonal crystal system.[3] Sapphire is found in nature usually in rough rounded pebble-like masses, though frequently outer crystalline forms are evident. The material is also made synthetically by the Verneuil[3] process.

Figure 1*B* shows a wooden model of a sapphire crystal of hexagonal prism shape. This shape is frequently found in nature. The axis of the long direction of the crystal is defined for the purpose of identification as the *C* axis and is the reference axis of the crystal that will be used for this discussion. This axis will be called the vertical axis and is parallel to the optic axis of the crystal. Figure 1*A* shows a cross section of a watt-hour meter jewel cup cut with the axis of the cup at right angles to the *C* axis. This cup is said to be oriented to an angle of 90 degrees ($\theta = 90$ degrees). Figure 1*C* shows another cross section of a cup where the *C* axis of the crystal and the axis of the

jewel cup coincide. The orientation angle is 0 degrees ($\theta=0$ degrees).

If a crystal is considered as being made up of small particles arranged in an orderly fashion, then a material that is noncrystalline, such as glass, may be thought of as being made up of particles with no systematic order of arrangement. A crystal that is allowed to form under ideal conditions will exhibit a definite geometric structure such as has been used in figure 1 to show one crystal form of sapphire.

If a sphere is formed from such a crystal as shown in figure 1, as might happen if it rolled in the bed of a stream for many years, it would be impossible to identify the substance as crystalline from its external shape. This is similar to what happens when synthetic sapphire boules are formed as they are more or less cylindrical in shape and exhibit few flat faces that make possible the identification of the boules as crystalline. Synthetic sapphire boules may give the appearance of globules of glass, yet actually they are identical in crystal structure to a piece of natural sapphire formed in nature which exhibits a perfect crystal shape as shown by figure 1. In the absence of the geometric form either optical methods[4] or X-ray[5] analyses can be used to orient and identify the crystal structure.

The most common method of identifying a sapphire crystal structure is to subject it to an analysis with polarized light and make use of the interference patterns which form definite optical figures.[4] The basal plane of the sapphire crystal may be determined by means of the optical figure. This is the plane in which all axes are equivalent. The axis at right angles to this basal plane is the vertical axis or *C* axis. This is the method of identification and orientation used in obtaining this experimental data.

Experimental Data

Following the publication of the material by V. Stott, it was desirable to check these results as the published data definitely indicated that an improvement in the life of watt-hour meter bearings could be obtained by controlling the orientation of the jewel cup to within the angle $\theta=80$ degrees to 90 degrees. It was impractical to set up life tests with watt-hour meter jewels with known orientations and run them for a period of five to ten years to get this information. There were available in the laboratory several hundred watt-hour meters which had been operated for periods of five to six years under known conditions with jewel cups that had been cut at random with respect to the crystal direction. The logical procedure was to discontinue some of these life tests, examine the bearings for wear, and determine the orientation of each individual jewel cup. A system of measuring the orientation angle was devised and approximately 150 bearings were taken from life tests and examined. The wear was estimated from measurements made by means of a calibrated eyepiece in a 40 diameter magnification microscope. These data are plotted as a composite curve in figure 2. Here the jewels were grouped in accordance with their orientation angle, and the circles represent the average wear value for a particular angular division. The minimum wear and the maximum wear for the angular division are shown by the crosses. It is interesting to note that there is a definite trend of increased wear as the jewels drop from an orientation of 90 degrees to an orientation of 0 degrees. In all cases the jewels oriented within 10 degrees ($\theta=80$ degrees to 90 degrees) showed minimum wear and fortunately 33 jewels were found within this angular range. Figure 2 includes bearings from life test watt-hour meters with both natural and synthetic sapphire jewel cups. A further breakdown of these data is shown by figure 3 which shows the results for the synthetic sapphire cups and figure 4 which shows the results for natural sapphire cups. All of the watt-hour meters from which these bearings were removed were operating to simulate normal load conditions and were equipped with high carbon steel pivots in well-lubricated bearings.

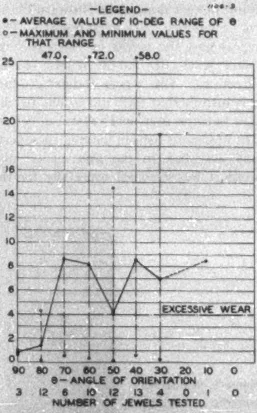

Figure 3. Jewel wear versus orientation

Composite curve of synthetic sapphire jewels

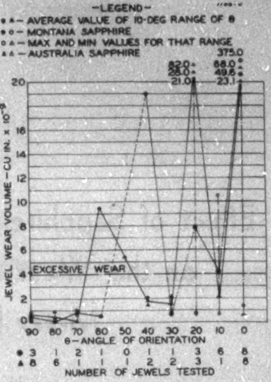

Figure 4. Jewel wear versus orientation

Composite curves of natural sapphire jewels

Natural Versus Synthetic Sapphire

The experimental evidence shows the desirability of controlling the orientation angle as advocated by V. Stott.[2] It is impractical to orient natural sapphire jewel cups due to the fact that natural sapphire is frequently found in small pieces so that it is possible to make but two or three jewel cups from a single piece of raw material. The synthetic sapphire boules are quite large, and it is possible to make many jewel cups from one boule. As the optical procedure for determining the crystal direction of a boule is identi-

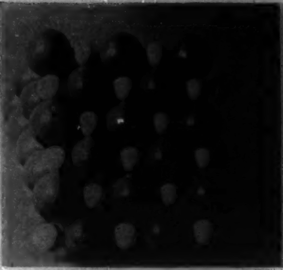

Figure 5. Atomic model of sodium chloride

Scale = two angstroms to one inch

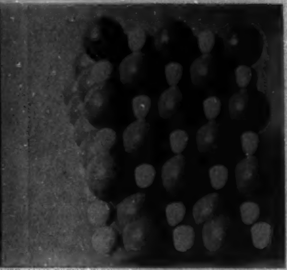

Figure 6. Atomic model of sodium chloride

Scale = two angstroms to one inch

cal with that required for determining the crystal direction of a small fragment of natural sapphire, it is obvious that it is much more expensive to make the determination for natural sapphire on a commercial basis than on synthetic sapphire.

A careful review of extensive life test data on watt-hour meter jewel cups of random orientation, operating at both accelerated and normal speed, had already led to the conclusion that taken as a whole, natural sapphire and synthetic sapphire were giving equivalent performance.

Theory of Orientation

It was suggested that the difference in wear exhibited by the jewel cups cut in the different crystal directions was due to a phenomenon known as translation gliding in crystals. This is demonstrated in certain crystals, as for example rock salt. If the crystal is placed under tension or compression under controlled conditions, one portion of the crystal moves with respect to the other along a plane and rupture does not occur. No fractures are discernible even with polarized light or X-ray diffraction after the crystal has been stressed, even though one portion actually overhangs another portion. A theoretical explanation for this is shown most clearly by figure 5 and figure 6. Figure 5 is an atomic model of salt (sodium chloride, NaCl) actually built to a scale of one inch equals two angstroms (125 million to one). The large balls represent atoms of sodium. An examination of the photograph will show the nesting of the sodium balls between the chlorine balls. The model pictured consists of two parts. The bottom is a single layer, and the top is a triangular pyramid. The model represents but a small part of a crystal and must be thought of as repeating itself in all directions to form a crystal of salt. If the pyramid portion is moved with respect to the bottom layer in any direction except the direction represented by the top and bottom of the page, it will be noted that the chlorine balls tend to ride over and onto the chlorine balls in the bottom layer. As the chlorine particles are negatively charged, we have two negatives coming together with the result that a repelling force is present. If they are forced to move in that direction, the result will be that the negative charges will force the crystal apart. If, however, the pyramid is moved in the direction of the top and bottom of the page, it will be seen, as shown by figure 8, that a new position is assumed which is identical in the relation of the sodium and chlorine balls to that shown by figure 5, except that a portion of the bottom layer has been exposed. This portion of the bottom layer that has been exposed represents, therefore, the portion that is overhanging. This is the crystallographer's explanation of gliding and is substantiated by accepted scientific proof based on X-ray diffraction studies. This is, of course, a very simple example and is not intended to serve as an explanation for the orientation wear effect in sapphire.

Sapphire material has a much more complex crystal structure than salt, which is of the cubic form, the simplest crystalline form known. A model of sapphire was built at the Massachusetts Institute of Technology, under the direction of Professor M. J. Buerger.[10] Figure 7 shows the sapphire model which was made to the same scale as the sodium-chloride model. In figure 7, the reference *C* axis is represented by a vertical line joining the two hands. Figure 8 shows how the model was built to separate. The top half of the model is separate from the bottom half and may be moved with relation to it. While it cannot be seen from the photographs, the model demonstrates that gliding can occur. The gliding is in a plane at right angles to the *C* axis in sapphire.

If the assumption is made that the phenomenon of gliding is an indication of loose atomic bonding on that particular plane, a possible explanation of the results obtained experimentally can be given. That is, particles of the crystal may be more easily removed in this plane of the crystal than in other planes, because the atoms are held more loosely in place than in other directions. Crystals may have more than one plane of gliding, but in sapphire, we are primarily concerned with the plane at right angles to the *C* axis as borne out by the experimental evidence.

The Dielectric Strength of Glass—an Engineering Viewpoint

E. B. SHAND
MEMBER AIEE

Synopsis: The purpose of this paper is to provide the engineer with co-ordinated information and data regarding the dielectric breakdown of glass which will permit him to apply this insulating material more effectively for high dielectric strength. In the discussion of the subject, particular attention has been paid to "edge effects" and other factors which cause wide variations in breakdown voltages—variations which are responsible for many of the seeming inconsistencies found in published results on the dielectric failure of glass and other materials.

The author has concluded that it is possible to make a reasonable approximation of the breakdown voltage of glass, if the conditions of the test or of the application can be sufficiently well determined.

The characteristic breakdown curves of this paper do not represent the results of any one series of tests, but are rationalized from data selected from many sources, including unpublished tests.

The data curves included refer mainly to Pyrex* glass, but corresponding data have also been included on electrical porcelain because of the interesting comparisons shown.

I. Dielectric Failure of Glass

Within the last few years the physicist has made pronounced progress in the study of dielectric failure, but in spite of this progress, our knowledge of the phenomena involved is still very incomplete. It is generally considered that the dielectric failure of insulating materials, such as glass and porcelain, may occur in one of two ways:

(*a*). In disruptive breakdown
(*b*). In thermal breakdown

Disruptive failure is one which results directly from an electrical overstress of the dielectric material without perceptible internal temperature rise. Recent research indicates that disruptive failure is caused by electronic ionization by collision within the molecular structure of the material.[1] In actual practice it is probable that pure disruptive failure occurs only under somewhat special conditions, and accurate test values of intrinsic dielectric strength are not easily obtained, even with the use of elaborate and careful procedure. The disruptive breakdown voltage is roughly proportional to the thickness, and may be expressed in volts per mil, or kilovolts per centimeter. Table I gives representative data for several materials which have been selected from various sources.

Table I. Disruptive Strength

Material	Disruptive Strength Kv/Cm. (Peak Value)
Lime glass	3,400– 4,500
Lead glass	3,100
Borosilicate glass (Pyrex)	3,900– 4,800
Fused quartz	5,000– 8,000
Electrical porcelain	320– 450
Mica	8,000–10,600

Thermal failure is one which results from the increased temperature of the insulation caused by the applied electrical stress. As the internal temperature rises the losses also increase, which, in turn, raise the temperature still more. Under certain circumstances a cumulative action of this kind may proceed until instability is reached, the current and losses rise suddenly, which represents the thermal failure of the insulation.[2]

Whether the limit of disruptive strength or that of thermal strength is reached first depends upon a number of conditions. In cases of thin glass sections, allowing the rapid dissipation of losses to the electrodes, of short periods of test, and of low ambient temperatures, the failure tends to be of the disruptive type; for the reverse conditions the failure tends to become thermal. When a series of tests is made with samples of successive steps of thickness, or at increasing temperatures, a transition from disruptive to thermal failure is found to

---

with a pivot bearing running in it.[6,7] Then assume a worn point on the pivot which is abrading the jewel surface. If the jewel cup is cut with an orientation $\theta=0$ degrees (figure 1), the pivot is abrading the jewel cup in the most favorable direction for removing material, and it is reasonable to expect that the pivot will find it easier to remove particles of the jewel cup than if the angle $\theta=90$ degrees. When $\theta=90$ degrees the pivot is abrading the crystal right angles to the favorable direction in which material can be removed and the particles of sapphire may be thought of as in a locked position.

Conclusions

The experimental evidence demonstrates that orientation is a definite factor in the wear of watt-hour meter jewel cups, and its control represents another step in insuring longer bearing life.

The experimental data confirm V. Stott's findings that for optimum results, the angle θ should be controlled to within $\theta=80$ degrees to $\theta=90$ degrees.

A possible explanation based on elementary crystal theory confirms the experimental evidence.

occur. Certain tests of this sort made on very thin samples of glass have indicated that this transition occurs abruptly. For thicker samples, such as would apply to engineering practice, the indications are that the internal temperature effects within the sample modify the characteristics of disruptive failure very materially before the conditions of thermal failure are reached so that the transition becomes much less apparent.

Curve 1 of figure 1 represents the pure disruptive breakdown voltage of a material such as glass or porcelain as a direct function of thickness. Curve 2 represents the breakdown voltage as modified by thermal effects. For the lower part of the curve the failure is still considered to be substantially disruptive, but for thick sections it will be purely thermal. No definite point of transition is indicated by this curve.

II. Factors Governing Breakdown

The principal factors governing breakdown may be listed as follows:

1. Characteristics of the dielectric material
2. Thickness of the section stressed
3. Temperature of the material
4. Duration of application of voltage
5. Characteristics of the applied voltage
6. Electrostatic field distribution in the dielectric and other "edge effects"

1. Wide differences in the characteristics of dielectric materials are indicated by the disruptive strengths listed in table I. Thermal failure is determined largely by the electrical and thermal conductivities of the material, and the variation of these properties with temperature. Glass and porcelain have widely different characteristics in disruptive failure, although in thermal failure these differences are much less pronounced.

2. The rate of change of breakdown voltage with thickness of section is dependent upon a number of conditions. As already stated, the breakdown voltage in pure disruptive failure may be considered to vary directly with the thickness. Mathematical analyses of thermal failure show that for thin sections the breakdown voltage will vary as $\sqrt{\text{thickness}}$, but that as the thickness is increased, this rate of increase is not maintained, and that a limiting condition is reached where a further increase in thickness will not result in any increase in the breakdown voltage. In other words there is a maximum voltage which a single thickness of insulation will withstand, regardless of its thickness. For Pyrex glass this limit has been calculated to be approximately 5×10^6 volts.

When materials such as glass and porcelain are immersed in insulating oil, this rate of change of breakdown voltage with thickness is determined mainly by the geometrical configuration of the insulator and the electrodes. For flat plates with thin electrodes, such as metal foil, the voltage will vary as $\sqrt{\text{thickness}}$ (see figure 1, curve 3). For power insulators of conventional design this ratio becomes approximately $(\text{thickness})^{0.7}$, as is indicated in figure 4.

3. Information regarding the quantitative effect of temperature on dielectric failure is not as complete as would be desired. However, various groups of data for both glass and porcelain indicate that in passing from room temperature (20 degrees centigrade) to 100 degrees centigrade, a reduction in breakdown voltage varying from 20 per cent to 40 per cent may be expected. At temperatures of 350 degrees centigrade or more these materials will have little remaining dielectric strength.

4. The period of time during which the voltage is applied to a dielectric is an important factor in determining the resulting breakdown voltage. Tests made under different procedures in this respect are not directly comparable. In general, it is found that for periods of stress extending from a few microseconds to an appreciable fraction of a second there is little change in the breakdown voltage, but from this point to a period of several minutes the reduction may be of the order of 50 per cent. Beyond this point to indefinite periods of time, further reductions are not great. This time characteristic of breakdown is probably connected with the stabilization of the internal temperature of the dielectric.

In figure 1, the disruptive strength (curve 1) represents the limit of breakdown voltage on impulse tests, curve 2 may be taken to represent the results of tests taken with the voltage raised continuously at the rate of 667 volts, rms per second, which is the standard procedure for insulator testing, while curve 2*A*, may be taken to represent the procedure of raising the voltage in one-minute steps, as is standard for apparatus testing. Curves 3*B*, 3, and 3*A*, are corresponding curves for other test conditions.

The breakdown voltage as measured by the one-minute hold test is usually of the order of 15 per cent to 25 per cent lower than when measured by the standard continuously rising voltage procedure.

5. The question of voltage, whether d-c or a-c, and if the latter, its frequency, must be considered. Evidence indicates that if the failure is purely disruptive, the breakdown is determined by the peak value of the voltage. However, the dielectric losses produced by alternating stresses, even at commercial frequencies, are much greater than the leakage losses caused by direct current, so that in the former case a lower breakdown voltage may be expected, except for very special conditions, such as where very thin sections are involved. For normal sections and commercial frequencies, this reduc-

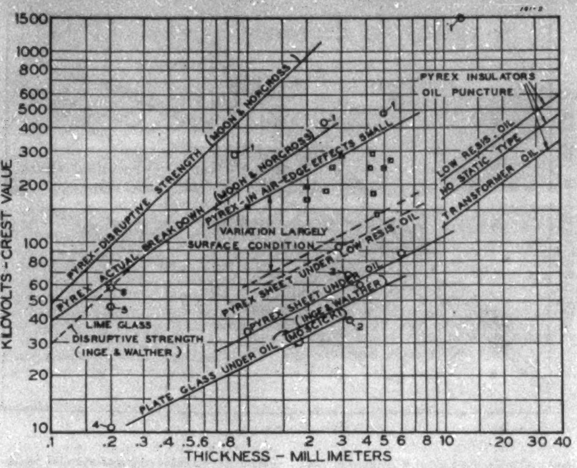

Figure 2. Selected dielectric breakdown data for glass

tion may be of the order of 20 per cent (peak value of the a-c voltage being considered).

As the frequency is increased the dielectric losses increase and the breakdown voltage drops. Some tests have indicated that at a frequency of 10,000 cycles the breakdown voltage may be about 40 per cent of that at 50 or 60 cycles, while for frequencies of the order of 1 megacycle this ratio may drop to less than 10 per cent.

6. In the actual application of insulation, it is not possible to avoid conditions which lead to local field concentrations and similar effects which reduce the breakdown voltage. These are generally referred to as "edge effects," because they were first observed at the edges of the electrodes, although they are not limited to these localities. Even in elaborate tests it is impossible to eliminate edge effects completely, and many discrepancies in the published data on the breakdown of glass result from this cause.

In addition to the edges of electrodes, these effects are found at points of imperfect contact between the electrode and the insulation, scratches in the electrode surface (when metal foil, or a silvered surface is used), voids or lack of homogeneity in the insulation itself, at changing sections of the insulation, and at imperfections of the surface of the dielectric, etc.

One of the principal reasons for the low disruptive strength of porcelain as compared with glass, is believed to be connected with the nonhomogeneous nature of the porcelain body which results in local field concentrations within the material. Glass, on the other hand, is homogeneous.[†] As a consequence of this, porcelain is much less sensitive than glass to certain edge effects of external origin. For instance in tests on glass it was found that with a rough ground surface under the electrodes, the breakdown voltage was only 16 per cent of the value obtained on a corresponding sample with polished surfaces. In the case of porcelain there was little difference in the two tests, and the breakdown voltages obtained on the porcelain samples were of the same order as those obtained on the rough ground glass samples of the same thickness.

Edge effects which result in local concentrations are ordinarily much less serious in the case of thermal failure than of disruptive failure. The temperature conditions resulting from the presence of local areas of high stress concentration will often produce a redistribution and partial equalization of stress, which does not occur when the failure is purely disruptive. Thus, within certain limits, thermal breakdown is in some degree analogous to the mechanical breaking of a ductile material such as soft steel, while the disruptive breakdown is more analogous to the tensile failure of a brittle material such as cast iron. Under certain conditions of test where edge effects are known to be present, a point of failure under the electrode, and away from the edges has been taken as indicative of a thermal failure, while a point of failure at the electrode edge or beyond the edge has been considered indicative of a disruptive failure. This distinction must be used with considerable care, as it is far from being a certain criterion to distinguish these conditions.

In order to avoid these edge effects it it important that the insulation used be without voids or surface imperfections, that the electrode should make a good contact with the insulation at all points, and that the stress at the electrode edges be equalized in some way. One effective method of reducing the edge stress is to thicken the insulation at the point where the electrodes terminate, without sudden changes in section.

Another type of edge effect not yet referred to specifically is one connected with certain phenomena in the ambient medium, such as insulating oil. Dielectric tests are frequently made under oil in order to eliminate flashover of the insulation sample. With the usual procedure for such tests, the electrostatic field at the electrode edges will fringe out into the oil. Insulating oils have a dielectric constant much lower than those of glass and porcelain so that the electrical stress in the oil will be materially higher than otherwise. Under these conditions corona discharges will form in the oil long before the true breakdown strength of glass is approached. As the voltage is raised beyond the corona point of the oil, streamers develop which will extend over the glass or porcelain. At the terminating point of these streamers on the surface of the insulation intense voltage gradients will exist, causing disintegration of the point attacked. If this action is allowed to continue for a sufficient time, it is probable that a hole will be drilled completely through thick sections of glass or porcelain causing dielectric failure.

This type of failure is determined almost entirely by the breakdown of the oil, and does not constitute a valid test of the insulating material, except for those cases where the insulation is to be oil-immersed in actual use.

Corresponding samples of various glasses and porcelain and of mica with wide differences of dielectric characteristics have been found to puncture at essentially the same voltage under this test, which demonstrates that breakdown is not a function of the properties of the insulating material.

[†] This, of course, is relative. Glass bodies may contain "stones, seeds, or blisters," which are not homogeneous with the remainder of the material. Any serious fault of this character, however, can be eliminated readily by visual inspection.

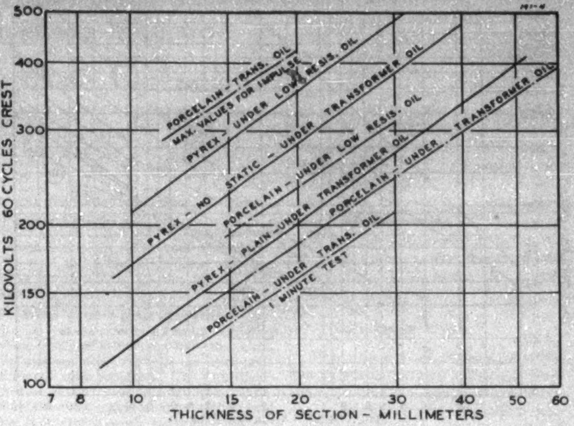

Figure 4. Oil puncture tests on power insulators

60-cycle voltage, raised continuously at 667 volts (rms) per second

Certain investigators state that when streamers occur in the oil the discharges have been found to be highly oscillatory, and that even if the puncture takes place under the area of the electrodes, the measured breakdown voltage may not be a true indication of dielectric strength because of the presence of the high frequency component of voltage.

One of the means used in overcoming this condition, at least to some extent, is by the use of semiconducting liquids in place of regular insulating oil. Oil with a high water content, mixtures of xylol and alcohol, etc., are effective in preventing the formation of corona to a very considerable extent. Semiconducting surfaces on the insulation adjacent the electrodes have also been used to produce the same general effect. In many practical applications the form of the insulation and the electrode can be selected so that the normal voltage stress in the oil is below its corona point. This procedure is commonly employed in the design of oil-immersed transformers. In this case, however, the insulation is usually composed of organic material.

There are still insulation test specifications which call for the oil immersion of the test piece, and many such tests of questionable validity are still made. For this reason an appreciation of the edge effects resulting from the ambient oil is of particular importance. As an instance of this, the oil puncture test is the standard procedure for testing power-line insulators, in spite of the fact that it is generally recognized that the results so obtained are not representative of their performance in service. Figure 4 gives average breakdown data as obtained from a large number of tests made on both Pyrex and porcelain insulators. The curves show that the puncture voltage may be raised either by reducing the resistivity of the oil or by using a semiconducting film on the insulator surface. Tests on Pyrex insulators indicate that, even when low-resistivity oil is used, the puncture results from edge effects, rather than from overstress of the glass.

III. Curve Data

Figure 1, representing the general dielectric characteristics of an insulating material such as glass or porcelain has already been discussed. It is to be noted, however, that a single group of such curves will not apply to all conditions. For instance, curve 1, the disruptive strength, may vary in some way with temperature. Curves 2 and 3 will shift to higher or lower voltages with variations of such factors as temperature, frequency, and duration of stress. These two curves represent certain limiting conditions of edge effect, so that for specific cases the relative severity of this factor must be estimated. This is necessarily very much of a guess, unless the engineer has a considerable background of experience to call upon. For actual design purposes there is the additional question of the proper factor of safety to be considered. This will, of course, depend upon the requirements of the type of application in view.

The data presented in the following figures refer to tests made at room temperature, and except when indicated otherwise, the values are for 60-cycle voltage raised continuously at the rate of 667 volts (rms) per second. In the case of some of the published data it was necessary to adjust the breakdown voltages to the condition. It will be noted, furthermore, that all voltages are expressed as peak values, rather than rms values.

Figure 2 includes a few representative

data for glass. These are mainly for Pyrex glass, although some values for lime glass are included.

The disruptive strength of Pyrex glass, and also the breakdown values as actually modified by temperature effects are taken from the data of Moon and Norcross.[3] The results indicated by the square points were obtained from tests made by the Corning Research Laboratory on pin-type Pyrex insulators with the heads ground thin and polished to permit their puncture in air without flashover. Voids between the outer electrode and the insulator head, together with other surface irregularities, produced edge effects which were largely responsible for the wide difference in the breakdown values shown. Values indicated[1] represent impulse tests on Pyrex samples. Edge effects were experienced in these tests as well.

Other tests of the Corning Research Laboratory on plate glass under oil (point 2) check closely with the early data of Moscicki.[4] These tests were repeated with the use of semiconducting oil, with the result indicated by point 3. Corresponding tests made on Pyrex plate are seen to give materially higher breakdown voltages. The reasons for this difference are probably the lower dielectric constant of this glass (which will reduce the field strength in the oil), and the higher thermal resistance of Pyrex glass.

Data on lime glass, points 4, 5, and 6, are taken from the many tests of Inge and Walther.[5] They are for the following conditions:

4. Tests made under insulating oil
5. Tests with edge effects eliminated; duration ten seconds
6. Tests with edge effects eliminated; impulse tests

The curves for Pyrex insulators in figure 2 are replotted from figure 4.

Figure 3 corresponds to figure 2, except that the data apply to porcelain. The disruptive strength of porcelain is roughly ten per cent that of Pyrex glass, but when the breakdown is measured under insulating oil, there is very little difference between the two materials. For thick sections, which tend to result in thermal breakdown, the values of glass and porcelain tend to approach each other, even when edge effects have been eliminated from the test.

Points marked 1 and 2, for immersion in low and high conductivity oil respectively, refer to one-minute tests, and are consequently lower in value than the breakdown voltages taken with continuously rising voltages.

Points 3, 4, and 5 represent data published by Bellaschi and Manning[6] on porcelain insulator shells,

3. One-minute hold tests
4. Tests made with continuously rising voltage
5. Represents the limits of breakdown on impulse tests

The curves on power insulators have been replotted from figure 4 which has been discussed already.

Figure 5 combines the dielectric characteristics of Pyrex glass and electrical porcelain on one sheet. These characteristics are indicated in the same manner as figure 1, and the data are taken substantially from figures 2, 3, and 4, with minor modifications.

The information correlated in these curves, and in the data on other specific conditions mentioned above, is admittedly not developed to a point where an accurate prediction of the voltage at which Pyrex glass and porcelain will fail under certain conditions of test or of practical application, but it is believed that rough approximations can be made, and furthermore, that the methods proposed will allow the insulation engineer to obtain a better oriented view of the problems involved, and how the materials discussed might be used to better advantage. It is also hoped that with time, additional test results will allow the approximations to be made with improved accuracy.

Overvoltages in Polyphase Induction Motors During Single-Phase Operation

C. MACMILLAN
MEMBER AIEE

G. K. CARTER
ASSOCIATE AIEE

Introduction

IN the course of the starting, reversal, or normal operation of a polyphase wound-rotor induction motor, it occasionally happens that either the stator or the rotor or both may be allowed to operate single phase. In some cases it has been noted that the voltage of the open terminal or terminals under these conditions has a steady-state peak value well above its normal maximum. While scattered references to this effect may be found in the literature, and though the general subject of single-phase operation of polyphase induction motors has been discussed from time to time, apparently the magnitude of these voltages has not been the subject of a thorough and organized investigation. This paper is based on the results of a study, undertaken to determine analytically the maximum theoretical voltages of a three-phase induction motor under single-phase operating conditions, and, so far as possible, to check these calculated figures against actual test results.

Conclusions

The following conclusions were drawn from this study, for motor operation only; in general, high-voltage conditions would be worse for generator operation:

1. When a three-phase induction motor is operated from single-phase lines, the voltage from the open to either of the active terminals cannot exceed its normal three-phase value.

2. When a three-phase wound-rotor induction motor is operated with one rotor line open-circuited, the voltage from this open terminal to one of the active rotor terminals may reach a theoretical maximum of 2.3 times the rotor open-circuit voltage, assuming zero rotor resistance. This maximum would occur if the stator phase rotation were reversed and the secondary resistance were about 1.3 times the total leakage reactance referred to the rotor. The ratio of 2.3 for the terminal voltages is somewhat reduced in case part of the secondary resistance is internal.

3. When a three-phase wound-rotor induction motor is operated from a single-phase supply with one rotor line open, high voltages can occur on both the rotor and the stator open terminals. The theoretical maxima of these voltages, with resistance and saturation neglected, occur slightly below synchronous speed and recur twice in each slip cycle. The maximum theoretical line-to-line voltage on the rotor is $\sqrt{3}X_m \div 2X_0$ times the normal open-circuit rotor voltage (peak values); that on the stator is $\sqrt{3}(X_m - X_0)/2X_0$ times the normal line-to-line stator voltage (peak values).

4. The rotor voltage is somewhat analogous to the armature voltage of a synchronous machine with a single-phase short circuit.[1] In fact, the expression given here for the rotor voltage agrees with a previously derived expression for the transient voltage of the open terminal of a synchronous machine.[2] The stator open-terminal voltage in the induction motor has no counterpart in the normal synchronous machine. The presence of transient voltages in the induction motor of even higher magnitude than the steady-state voltage seems to correspond to the synchronous machine case when switching occurs at such time as to trap a d-c flux component in the short-circuited winding.

5. The magnitudes of voltages usually experienced are much lower than those calculated, because of various factors such as resistance, saturation, and supply system impedance, which were omitted to make the calculations feasible. In motors of small internal percentage resistance, the calculated values are most closely approached.

6. The conditions of operation and the abnormal voltages discussed in this paper can and do occur with existing systems of control of wound-rotor induction motors. They may be aggravated in cases in which one or the other of the open circuits is of a vibratory, or rapidly recurring, nature. An easy and effective safeguard is to avoid opening completely any one of the rotor lines, as tests show the voltages to be greatly reduced with even a relatively high resistance in the odd rotor phase.

Theoretical Investigations

A. SINGLE-PHASE STATOR

The three-phase induction motor with single-phase excitation has long been studied from several standpoints: as a special case of an unbalanced polyphase machine,[3,4,5] as one type of single-phase motor,[6] and as a single-phase to three-phase phase converter.[7] Operation of this nature may readily be visualized by means of the revolving-field theory of Ferraris and its equivalent expression in terms of symmetrical components or by means of the two-axis method of resolution.[8] Both theoretical considerations and experience show that for this type of operation the open stator terminal will not reach a steady-state voltage greater than normal, so long as the rotor is symmetrical or nearly so.

B. SINGLE-PHASE ROTOR

When a three-phase wound-rotor induction motor is operated with three-phase excitation and a single-phase secondary, the analysis becomes somewhat more difficult than for the case just considered. Nevertheless, adequate solutions have been obtained by the method of symmetrical components[4,5] and by the two-axis method;[9] this is also a special case of "internal cascade" operation,[10] in which tertiary nonsynchronous currents flow through the supply system, and are determined by its total impedance.

For purposes of visualization, with a sinusoidal terminal voltage the stator impressed field is of constant magnitude and rotates at synchronous speed with respect to the stator; thus, neglecting the resistance and leakage reactance drops, a maximum of twice normal voltage could be induced in the rotor if the stator phase rotation were reversed suddenly while the rotor was turning at full speed. A finite impedance connected between two of the rotor terminals allows a single-phase secondary current to flow with no direct mutual reaction on the open rotor phase, which thus keeps substantially twice normal induced voltage. Assuming zero machine resistance and a noninductive secondary resistor, the approximate secondary voltage vector diagram would be as indicated in figure 1, in which point 1 represents the open rotor terminal and points P and Q the rotor terminals shorted through the external resistor, point O being the center of the resistor. As the secondary resistance varies from infinity to zero, P and Q trace out the semicircles indicated. The maximum line-to-line voltage thus is seen to be about 2.3 times normal, for an external resistance of about 1.3 times the total leakage reactance. To account for the rotor resistance, points P and Q should be located on the same line, but a little closer together; they thus trace out

curves slightly inside of the semicircles shown.

The conclusions drawn from this visualization are confirmed by an analysis by the two-axis method (appendix *A*).

C. Single-Phase Rotor and Single-Phase Stator

The operation of an induction motor with single-phase stator and rotor has been the subject of study for some time, both qualitatively and quantitatively. Steinmetz[7] discusses this connection under the heading of reaction machines, of which it is one type, and points out a number of interesting characteristics particularly associated with synchronous operation. Lyon[4] makes an analysis by symmetrical components, applying principles found useful in the case of the other types of single-phase operation. This analysis has been extended in a later paper,[11] which gives the equivalent circuit in the form of a ladder network.

Kron[9] has indicated symbolically the analytical solution in terms of a two-phase machine. A similar analysis may be based on the three-phase machine equations of Stanley,[12] also a two-axis resolution. Solutions by both of these methods were carried out for this study, resistance and saturation being neglected. The steady-state solution of Stanley's equations is outlined in appendix *B*. This solution indicates that the maximum voltages occur at a speed slightly below synchronism and are repeated twice in each slip cycle. The shapes of the calculated rotor and stator voltage waves at two points in the slip cycle are shown in figures 2 and 3. The maximum line-to-line voltage for the rotor is $\sqrt{3}X_m/2X_0$ times normal peak line-to-line voltage; for the stator, the ratio is $\sqrt{3}(X_m-X_0)/2X_0$.

In order to visualize the machine conditions corresponding to this state of operation, reference may be made to figures 4 and 5, which represent diagrammatically the physical arrangements of the machine parts and the approximate flux relations.

The voltages include components due to (*a*) transformer effects and (*b*) their modification due to speed of rotation. The first component is most easily recognized in the stationary condition. At any angle θ between the magnetic axes of the single-phase rotor winding and single-phase stator, the former may be assumed replaced by two quadrature coils in series, one of which is in maximum inductive relation to the stator winding, the other in noninductive relation with the excited stator phase, but in maximum inductive relation with the idle stator winding. There is thus a double transformation of stator impressed voltage into the idle stator and rotor windings involving a ratio of transformation dependent upon the angular position of the rotor axis, as illustrated in figure 6. With this variation of transformer ratio there is a corresponding variation of flux density, and of the additional voltage due to speed under running conditions.

When the motor is running, the machine voltages may be thought of as consisting of a speed voltage and also a transformer voltage. Since the curves of induced voltage of figure 6 might be thought of as proportional to the curves of "total flux of induction" for the open coils, the maximum speed voltage at any rotor angle, for constant rotor speed, may be thought of as proportional to the slope of these curves, or to the rate of change of "total flux of induction" with respect to angle (i.e., time). To this speed voltage must be added the transformer voltage itself; and for line-to-line quantities the effects of the excited phases must be considered.

Comparison may now be made with the calculated voltage curves of figures 2 and 3. It is seen that the high-voltage curves fall off from their maxima to zero in about 17 degrees, as shown by the slopes in figure 6. They then acquire smaller negative values, which are appreciably shifted by the transformer and excited-phase voltages.

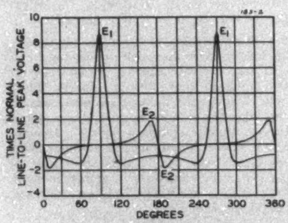

Figure 2. Calculated rotor voltage waves, single-phase rotor single-phase stator, $L_m/L_1 = 10$

E_1—At instant of maximum peak voltage
E_2—At one-quarter slip frequency cycle later

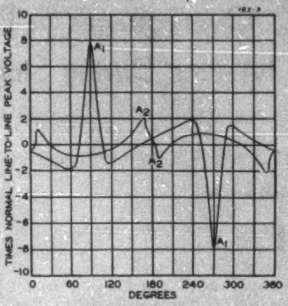

Figure 3. Calculated stator voltage waves, single-phase rotor single-phase stator, $L_m/L_1 = 10$

A_1—At instant of maximum peak voltage
A_2—At one-quarter slip frequency cycle later

It is important to note from this analysis that, although very high voltages may exist, they are not the result of correspondingly high fluxes but of high rates of change of flux. Consequently, the effects of saturation will not be so great as might be supposed. The stator resistance should slightly reduce the magnitude of the currents and fluxes and introduce some phase shift; normal rotor resistance would also be expected to have a relatively small effect, but large values of external resistance would appreciably alter the impedance and result in lower voltages.

Of more importance in many practical cases is the impedance of the power source. This in effect adds to the motor impedances and reduces the current and voltage peaks accordingly. Including transformers as part of the source, the larger the system relative to the motor, the more closely are the theoretical voltage ratios approached.

Experimental Results

Tests were made on a standard three-phase wound-rotor induction motor rated 30 horsepower, 1,200 rpm, 60 cycles, 220/440 volts; the ratio X_m/X_0 for this machine, by test, was 12.8; the ratio of total resistance to total leakage reactance was 0.25. For some of the tests a

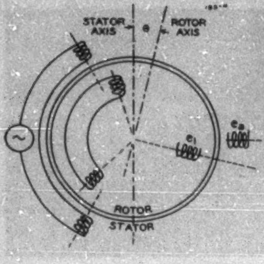

Figure 4. Diagrammatic sketch of three-phase induction motor operating single-phase on both stator and rotor

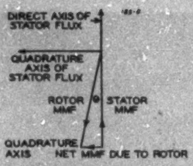

Figure 5 (above). Diagram illustrating vector flux and magnetomotive force relations of figure 4

standard cam-operated controller was used, to simulate operating conditions; in other cases knife switches were used, to give more positive control of the timing.

Prior to the running tests, curves of induced voltage versus rotor position were taken. For these, the stator was excited at a fixed voltage and all line-to-line voltages were measured by voltmeter as a function of rotor position, readings being taken with the rotor blocked. Since in some cases short-circuited rotor phases were involved, only one-fourth rated voltage was applied.

For the running tests, the motor was operated without load, giving a normal speed slightly below synchronism. Observation by means of a cathode-ray oscilloscope gave sufficient confirmation of the analysis for the two cases of three-phase single-phase operation to permit restriction of the further work to the more troublesome case of single-phase single-phase operation. For that case, the magnetic oscillograph was used to furnish permanent records.

Table I shows the comparison of the test and calculated voltage ratios, all on a line-to-line basis, for the single-phase single-phase case. All of these are steady-state voltages; in some of the oscillograms there was evidence of initial transient voltages, higher than the steady-state voltages, which appeared to build up under contactor vibration. Records of this sort of transient condition were obtained only for some of the lower voltage conditions in table I, the maximum observed transient peak being about 30 per cent greater than the corresponding steady-state peak.

Sample wave forms are shown in figure 7, which may be compared with the calculated wave forms of figures 2 and 3.

The tests indicate that resistance, in the normal range, slightly lowers the voltages. The effect of saturation is not indicated for the running condition, though this may be the explanation of the unusual standstill voltages (measured by voltmeter). System impedance, as shown by the effect of removal of the transformer, may modify the peaks to a large degree. Even without the transformer, however, the impedance of the system used was relatively high, resulting in the impressed voltage distortion evident in figure 7.

Table I. Test and Calculated Line-to-Line Voltages for Single-Phase Single-Phase Operation

	Rotor	Stator
Standstill: Ratios of rms voltages		
Calculated	1.61	1.93
Test	1.85	2.15
Running: Ratios of peak voltages		
Calculated (for an infinite bus)	11.1	10.2
Test: Motor connected direct to lines; rings shorted	5.0	4.45
Motor connected through transformer; rings shorted	3.35	3.05
Transformer in; external resistance in rotor circuit four times rotor resistance	3.0	2.55
Transformer in; rings shorted; odd rotor line tied to shorted rings with 300 times rotor phase resistance	1.1	1.0

Well-marked depressions in the supply voltage (wave *B*, figure 7), occurring simultaneously with maximum peak voltages in stator and rotor open phases, indicate the effect of limited supply system capacity in reducing the latter test voltage below calculated values. The wave shape is modified by this and other factors, so that the best comparison with calculated wave shape *A* (figure 3) is not obtained with the maximum induced voltages but at intervals of several impressed voltage cycles earlier or later, where the distortion at the peak has diminished. At these intermediate points in the quarter slip cycle between A_1 and A_2 states (figure 3), the similarity between the oscillogram and the calculated wave shape A_1 may be recognized more clearly despite the relative reduction of the oscillogram peak value.

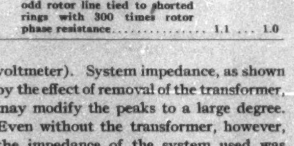

Figure 6. Ratio of induced voltage in open phase to normal phase voltage, as a function of rotor angular position for $L_m/L_l = 10$

Appendix A. Maximum Voltage for Single-Phase Rotor in Three-Phase Stator

The two-axis resolution suggested by Stanley[11] will be applied. Stator resistance is neglected and the rotor resistance is combined with the external resistance, giving a total of r per phase; secondary terminal voltages are taken to the middle of the secondary resistor. With balanced stator terminal voltage (an infinite bus) and with rotor terminal 1 open, the conditions for equations 16 of reference 12 are

$$e_a = V \sin \omega t$$

$$e_b = V \sin (\omega t - 2\pi/3)$$

$$e_c = V \sin (\omega t + 2\pi/3)$$

$$i_a + i_b + i_c = e_2 - e_3 = i_1 = i_2 + i_3 = 0$$

The equations thus become

$$L_0 p i_a - \frac{2\sqrt{3}}{3} M_0 p(i_2 \sin \theta) = V \sin \omega t$$

$$-\frac{\sqrt{3}}{3} L_0 p(i_a + 2i_c) + \frac{2\sqrt{3}}{3} M_0 p(i_2 \cos \theta) = -V \cos \omega t$$

$$M_0 p i_a - \frac{\sqrt{3}}{3} M_0 [p\theta](i_a + 2i_c) - \frac{2\sqrt{3}}{3} l_0 (\sin \theta) p i_2 = \frac{2}{3} e \cos \theta + \frac{2\sqrt{3}}{3} r i_2 \sin \theta$$

$$-M_0 [p\theta] i_a - \frac{\sqrt{3}}{3} M_0 p(i_a + 2i_c) + \frac{2\sqrt{3}}{3} l_0 (\cos \theta) p i_2 = \frac{2}{3} e \sin \theta - \frac{2\sqrt{3}}{3} r i_2 \cos \theta$$

where

$$e = e_1 - e_3$$

These equations may be integrated, giving steady-state solutions for e and i_3. The actual terminal voltages are given by $e_R = (e_1 - e_3) \pm r i_3$. These voltages are shown in the vector diagram, figure 1. The maximum for motor operation is obtained for $[p\theta] = -\omega$, when

$$e_R = \frac{3M_0}{L_0} V \sin 2\omega t \pm \frac{\dfrac{\sqrt{3}M_0}{L_0} V r \sin (2\omega t - \beta)}{\sqrt{4\omega^2 \left(\dfrac{M_0^2}{L_0} - l_0\right)^2 + r^2}}$$

$$\beta = \tan^{-1} \frac{-r}{2\omega\left(\dfrac{M_0^2}{L_0} - l_0\right)}$$

Figure 7. Oscillogram of operating conditions with single-phase stator excitation and with single-phase short circuit on rotor; 30-horsepower, 12,00-rpm, 3-phase, 60-cycle, 220/440-volt induction motor

A—Stator line-to-line voltage
B—Stator line-to-line voltage (impressed)
C—Stator line-to-line voltage
D—Rotor line-to-line voltage
E—Rotor line-to-line voltage

For measured peak values, see table I

The peak value of normal rotor line-to-line voltage, obtained by setting $[p\theta]=0$ and $r=\infty$, is $|e_R|=\sqrt{3}M_0V/L_0$. Also the short-circuit inductance referred to the rotor is $l_l=l_0-M_0^2/L_0$. Thus,

$$\frac{e_R}{|e_R|}=\sqrt{3}\sin 2\omega t\pm\frac{r\sin(2\omega t-\beta)}{\sqrt{r^2+X_l^2}}$$

$$\beta=\tan^{-1}r/X_l$$

As r varies from 0 to ∞, the diagram of figure 1 is traced out.

Maximum voltage occurs for $r/X_l=1.33$; it is $e_R/|e_R|=2.30$. If part of r is internal to the machine, that fraction of the resistance drop is subtracted (vectorially) from the terminal voltage.

Appendix B. Maximum Voltage for Single-Phase Rotor in Single-Phase Stator

Stanley's equations will be applied to this case, as in appendix *A*, assuming sinusoidal applied voltage (an infinite bus) with all resistance neglected. The terminal conditions then are

$$i_1=i_a=i_2+i_3=i_b+i_c=e_2-e_3=0$$

$$e_b-e_c=V\cos\omega t$$

The equations to be solved are as follows:

$$\frac{-2\sqrt{3}}{3}M_0p(i_2\sin\theta)=e_a$$

$$2L_0pi_b+2M_0p(i_2\cos\theta)=V\cos\omega t$$

$$M_0[p\theta]i_b-l_0(\sin\theta)pi_2=(\sqrt{3}/2)e_1\cos\theta$$

$$M_0pi_b+l_0(\cos\theta)pi_2=(\sqrt{3}/2)e_1\sin\theta$$

Finally evaluated, the steady-state phase voltages are the following:

$$e_1=\frac{\dfrac{l_0V}{\sqrt{3}\,M_0}}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}\left\{\sin\theta\cos\omega t+\left[\frac{p\theta}{\omega}\right]\cos\theta\sin\omega t-\frac{2\left[\dfrac{p\theta}{\omega}\right]\sin^2\theta\cos\theta\sin\omega t}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}\right\}$$

$$e_a=\frac{\dfrac{V}{\sqrt{3}}}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}\left\{(1/2)\sin 2\theta\cos\omega t+\left[\frac{p\theta}{\omega}\right]\cos 2\theta\sin\omega t-\frac{(1/2)\left[\dfrac{p\theta}{\omega}\right]\sin^2 2\theta\sin\omega t}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}\right\}$$

The line-to-line voltages are

$$e_R=(3/2)e_1$$

$$e_S=-(3/2)e_a\pm(1/2)V\cos\omega t$$

Maximum values for e_R occur when $\cos\theta=\pm 1$, $\sin\omega t=1$; then

$$e_{R\max}=\frac{\dfrac{\sqrt{3}\,l_0}{2M_0}V}{\dfrac{L_0l_0}{M_0^2}-1}$$

Maxima of e_S occur when $\cos 2\theta=\pm 1$, $\sin\omega t=1$; then

$$e_{S_{\max}}=\frac{\dfrac{\sqrt{3}V}{2}}{\dfrac{L_0l_0}{M_0^2}-1}$$

Calling the stator self-inductance L_0 the magnetizing inductance L_m, and the short-circuit inductance $L_0-M_0^2/l_0$ the total leakage inductance L_l, the ratios of the peak voltages as calculated to the normal peak voltages are

$$\frac{e_R}{|e_R|}=\frac{\sqrt{3}}{2}\frac{L_m}{L_l}$$

$$\frac{e_S}{|e_S|}=\frac{\sqrt{3}}{2}\left(\frac{L_m-L_l}{L_l}\right)$$

The former corresponds to equation 24*f* of reference 2.

In practice, the motor may not be connected to a system of low enough impedance to be taken as an infinite bus. In this case, if the generated internal voltage is substantially constant, it may be taken as the source, with the generator reactance transferred to fictitious motor circuits; the generator and line reactances would be expected to have approximately the effect of additions to L_m and L_l in the voltage expressions, giving

$$\frac{e_R}{|e_R|}=\frac{\sqrt{3}}{2}\frac{L_m+L_{ext}}{L_l+L_{ext}}$$

$$\frac{e_S}{|e_S|}=\frac{\sqrt{3}}{2}\frac{L_m-L_l}{L_l+L_{ext}}$$

These voltages would apply to fictitious points within the generator; the actual motor terminal values would differ slightly.

The standstill, or transformer, voltages can also be obtained from the foregoing expressions by setting $[p\theta]=0$. Then the line-to-line voltages to the open terminals are

$$\frac{e_R}{|e_R|}=\frac{\dfrac{\sqrt{3}}{2}\dfrac{L_0l_0}{M_0^2}\sin\theta}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}$$

$$\frac{e_S}{|e_S|}=\frac{\dfrac{\sqrt{3}}{4}\sin 2\theta}{\dfrac{L_0l_0}{M_0^2}-\cos^2\theta}\pm\frac{1}{2}$$

The respective maxima are

$$e_R=\frac{\sqrt{3}L_m}{4\sqrt{L_l(L_m-L_l)}}$$

$$e_S=\frac{1}{2}+\frac{\sqrt{3}(L_m-L_l)}{4\sqrt{L_mL_l}}$$

T. E. BROWNE, JR.
ASSOCIATE AIEE

I. Introduction

THE importance of fluid flow in aiding arc extinction in circuit interrupters has long been known. Two general types of explanation of the large effect found have been offered. Slepian[1,2,3] who seems to have been the first to stress the importance of the motion of the gases liberated by the arc from the surrounding oil or solid insulation in oil breakers and expulsion fuses, sought the explanation in reduced arc section at current zero, and increased diffusion rate of ions and molecules arising from the turbulence. Other investigators have expressed similar views, at least in part.[4,5]

Another theory attributes the rapidly rising dielectric strength at current zero to the cutting of the arc path by a film of cool, un-ionized fluid, which grows in thickness at a rate comparable with the fluid velocity, so that a simple relation may be expected between fluid velocity, fluid dielectric strength, and limiting recovery rate of circuit voltage at which extinction takes place. Such a relation is said to have been established experimentally for an oil flow breaker,[6,7,8] but this has not been universally accepted.[9]

Figure 3. Arc photographs under water

With this uncertainty as to the nature of the arc extinction process in fluid flow, it is highly desirable that direct experimental investigation be made into the state of the arc near current zero. Short exposure photography near current zero would seem to be a powerful means of attack. High-speed motion pictures, at 5,000 frames per second, have been taken of arcs in a gas blast.[10,11] These show greatly reduced arc sections arising from the blast, but fail to show conclusively any sharp dividing line between a rapidly receding highly ionized luminous region and a growing dark region corresponding to freshly introduced gas in the arc path. Also, a criticism might be made that the location of the current zero is not determined with respect to the pictures. One cannot be certain that the continuous luminous column representing the arc space may not have existed for many microseconds after current zero, since it is quite possible that such a fine column, subjected to the local microturbulence inherent in the gas blast and high-temperature gradients, might have the capacity to withstand considerable voltage without breakdown.

Hoping to shed more light on these questions, particularly for the case where the flowing fluid was liquid, a series of investigations were carried on at the Westinghouse Research Laboratories, of which this is the first report.

The immediate objectives of this research were: (1) to determine the effect on the arc's interrupting ability of independent variations in fluid velocity, static pressure, type of fluid, arc length, electrode shape, baffle arrangements, and circuit natural frequency; and (2) to photograph the arc under these controlled conditions, hoping thus to learn something about the actual mechanism of the interaction between the flowing liquid and the arc in its gas bubble, especially near current zero. In this paper only the photographic results will be described.

II. Apparatus

An arc drawing structure with associated pump was so designed and built that the arc could be subjected momentarily to either longitudinal or transverse oil or water velocities up to 200 feet per second in a 3-inch channel and to independently controlled static pressures up to 15 atmospheres. Figure 1 shows the general arrangement of the structure. The fluid is directed upward from the horizontal pump cylinder through a Micarta and glass liner within the vertical tube and into the discharge tank above. Windows are provided on opposite sides of the arc tube at the point where the arc is drawn.

For photographing the arc, a miniature camera is mounted in front of one of the windows, as shown in figure 2.[12] It is provided with the synchronously driven rotating shutter shown for taking pictures of the arc and its associated gas bubble at any point on the current cycle. Contacts on a rotating drum attached to the shutter disk serve to synchronize the camera shutter with it and to record on an oscillogram exactly when the picture was taken. Because of the importance of that moment, pictures were taken generally at or near to current zero, the exposure time (with a much narrower slit than shown) being about $^{1}/_{8,000}$ second. The arc bubble was shown in silhouette against a very brightly illuminated background. In addition to the magnetic oscillograph, a cathode-ray oscillograph was available for observing the arc reignition or extinction voltage at current zero. A few high-speed moving pictures of the arc at about 2,000 frames per second were also taken.

III. Results

Such a large number of arc photographs have been taken that only a summary of the observations illustrated by a few samples can be presented here. Five hundred-ampere arcs, 1 and 2.5 centimeters long between one-fourth-inch (0.635 centimeter) electrodes subjected to parallel flowing oil and water were studied first. The bubble shapes with oil and water were apparently identical, but because of greater transparency and the absence of carbon, the photographs with water were generally clearer than those with oil.

Parallel Water Flow

In figures 3 and 4, photographs 272, 273, 274, 237, and 284; are all of tests with parallel water flow. All were taken with the shutter adjusted to open near current zero. In 272, taken at current zero, the velocity (11 feet per second) is so low that droplets of incandescent copper can be seen falling against the flow and the gas bubble, or cloud, is large. In 273 the velocity was slightly greater and the photograph was taken nearly 0.001 second after the arc had been extinguished by opening the "back-up" circuit breaker. Here, streaks of light indicate that the arc terminals were still white hot, and it is evident that the fluid had not yet completely closed in between the electrodes, even though nearly 1,000 microseconds had elapsed since the disappearance of the arc. In 274, taken under similar conditions but one half-cycle after arc extinction, the interelectrode space had been swept clear except for a trail of bubbles still arising from the lower arc terminal. Remnants of the gas bubble were still visible around the upper electrode. The conditions of 237 were similar to those of 273, except that the velocity was considerably greater. Here no incandescence can be seen at the arc terminals, but some of the background light was transmitted through the "neck" of the bubble still existing between the electrodes. Comparison with 273 shows that the increase in velocity resulted in a still smaller tendency for the flow to close in above the lower electrode. This effect of fluid velocity is even more clearly illustrated by 284, in which, at a still higher velocity, the gas bubble at current zero just filled the space in the "wake" of the lower electrode and extended almost unchanged in section all the way to the upper electrode, which was 2.5 centimeters away instead of 1 centimeter, as in the foregoing pictures.

Of especial importance for the theory is the fact that the arc interrupted the 4,600-volt reactive circuit here, showing that this gas bubble of about one-fourth inch diameter was able to withstand $\sqrt{2}\times 4{,}600 = 6{,}500$ volts or a gradient of 2,600 volts per centimeter, shortly (less than 400 microseconds) after this current zero without the aid of any interposed layer of liquid dielectric. Actually, the oscillogram of the test showed that the arc restruck one half-cycle later, presumably by thermal breakdown of the water[13] which must have by then entirely displaced the original gas bubble.

Nonparallel Water Flow

In addition to parallel flow, many other more complicated flow arrangements were studied. The first and simplest directing structure was merely a thin one-fourth inch thick) brass diaphragm placed across the flow channel and provided with a central round hole (usually one inch in diameter) through which the arc was drawn by the one-fourth-inch rod electrodes. Its location with respect to the electrodes in early tests is shown in photograph 299 of figure 4, taken one half-cycle after interruption of the circuit by the arc. The flow conditions roughly approximate those with many forms used in practice. Photo. 301, taken just before current zero, is the clearest obtained of a bubble form very often observed under these conditions, pear-shaped with the constricted neck only partially filling the outflow orifice. In contrast is 302, which was taken under apparently almost identical conditions, but which is entirely different. Such random variation in bubble size and shape was found to be characteristic of this type of flow at these moderate velocities. That bubble size was not, as one might expect, a function of instantaneous current is further shown in figure 5, by photograph 356, which was taken at peak current under otherwise similar conditions and shows a bubble of almost the same size and shape as that of 301 where the instantaneous current was near zero.

Associated with the variation in bubble

size was the variable interrupting performance of the arc under these conditions from one half-cycle to the next. The correlation between bubble size at current zero and tendency for the arc to reignite is illustrated well by photographs 301 and 302. Even though the circuit voltage in the case of 302 was 4,600 as compared with 2,300 for 301, the arc was extinguished after 302, but restruck with no appreciable pause after 301. Clearly, as one might expect, the small bubble was a very much better arc extinguisher than the large bubble.

FLOW OSCILLATIONS

These wide and apparently random variations in bubble volume and interrupting ability at current zero are apparently due to the characteristically oscillatory nature of the flow of liquid and gas around the arc and through an orifice. These oscillations, which were first revealed by large-amplitude pressure variations in the vicinity of the arc and by corresponding periodic arc voltage peaks, always occurred when the conditions were such as to permit the formation of an appreciably large gas bubble on the high-pressure side of the orifice. The frequency, usually a few hundred cycles per second, depended linearly on the maximum fluid velocity through the orifice and was relatively independent of the orifice size and shape, and also of the arc current and arc length. The relation was $f = 5V$ cycles per second, where V is the fluid velocity in feet per second. There was little, if any, tendency for the oscillation to synchronize itself with the 60-cycle current. Analysis of the oscillographic pressure records and of the mechanics of the flow indicated that periodic growth and collapse of the gas bubble surrounding the arc was an essential part of the oscillation.

Because of the lack of synchronization of the bubble oscillation with the current zero, the bubble diameter existing at current zero would be expected to vary in a random manner as it did in fact. Variability in interrupting performance was thus also explained. This oscillation could be prevented at moderate currents by so proportioning the flow channel and adjusting the driving pressure that bubble growth in front of the orifice was effectively prevented. Such arrangements gave somewhat better average interrupting performance with water but not with oil.

PHOTOGRAPHS WITH OIL

Photographs 805, 806, 890, 975, 989, 990, 991, and 976 of figures 5, 6, and 7 are samples of a great number obtained while studying the interrupting ability of the arc with oil flow directed by variously shaped orifices. As these orifices were made of a transparent plastic material (Lucite), the effect of a cross-section view was obtained. Photographs 805 and 806 were taken under nearly similar conditions, except that 805 was at the last current zero and 806 followed the last current zero by one half-cycle. In 805, the arc bubble is comparatively small, but still large enough so that the flow was oscillatory. In spite of the design to accentuate radial flow, 806 shows that the flow had not completely closed in over the lower electrode even after one half-cycle, and that the arc terminal there was still luminous. Somewhat in contrast is 890, taken only $^1/_{20}$ half-cycle (400 microseconds) after extinction of a 2,000-ampere arc in an orifice of different shape. The arc terminals were still glowing brightly but the interelectrode space appears to have been swept almost clear of gas even at this comparatively low velocity of 22 feet per second (11 feet per second at the tip of the lower electrode).

A still different electrode and orifice arrangement is shown in photographs 975 and 976 referred to above. These apparently show successive stages near the beginning of the growth of an arc bubble. Strangely, extinction occurred after 975, but not after 976. All of these pictures illustrate the characteristically very large random variations in appearance of arc bubbles with orifice flow and these last also show the frequent impossibility of distinguishing between bubbles in which the arc will just reignite and those in which the arc will just fail to reignite. This lack of distinction was characteristic of bubbles, whose volumes were always kept small by the flow, such as those in photographs 989, 990, and 991. These were all taken under identical conditions, except for the oil velocities, which were 209, 169, and 127 feet per second, respectively, measured at the constriction, which was here occupied by the arc. At the highest velocity some diminution in the bubble section may be noticed; but at 169 feet per second and 127 feet per second, which values were, respectively, above and below the critical value for ultimate arc extinction (143 feet per second), there was no detectable difference in the arc bubble appearance. However, it should be noted that photograph 990 was taken at a current zero prior to arc extinction.

More recently, sequence pictures have been obtained with a rotating-prism type high-speed motion picture camera[14] which reveal this bubble behavior clearly. The eight-frame sequence of figure 8 shows the gradual growth, collapse, and regrowth of an arc bubble under conditions similar to those of photographs 301 and 302 except that the fluid was oil flowing through the orifice at 68 feet per second, nearly twice as fast as in 301 and 302. The interval between successive pictures was about $^1/_{19}$ of a half-cycle, or 430 microseconds. Examination of the whole film leads to the conclusion that the current passed through a zero value in the vicinity of frames 4 and 5. Figure 9 is a similar sequence of an arc bubble like those of photographs 975 and 976 but also under oil flowing at considerably higher velocity. This sequence does not embrace a current zero. It is now revealed that photographs 975 and 976 represent near-minimum arc bubble sections which approximately coincided with current zeros only by coincidence.

IV. Conclusions

From a study of many hundreds of arc photographs represented here by only a few samples, the following conclusions have been drawn:

1. The gas bubble surrounding an arc under a flowing liquid is generally not displaced by a liquid barrier until some appreciable fraction of a half-cycle after the arc has been extinguished.

2. The existence of a large bubble section at current zero favors reignition of the arc while the existence of a small section favors its extinction.

3. Even under apparently identical conditions, the shape and size of the gas bubble may show very wide variations. These variations are the result of rapid bubble oscillations which are usually not synchronous with the arc current variation.

4. Where the arc bubble is uniformly small, there is no consistent difference between its appearance at a current zero at which the arc is extinguished and one at which it reignites, or between the characteristic bubble appearance at pressures or velocities just above the critical values for extinction and those just below these values.

With regard to the theory, it may be seen that conclusions 1 and 4 are wholly at variance with the idea that arc extinction *results from* the formation between the electrodes at current zero of a growing barrier of dielectric liquid. These and conclusion 2 suggest, rather, that extinction or reignition of the arc is usually determined by conditions existing within the remanent gas bubble at or just before current zero. These conditions probably relate to the character of the gas flow within the bubble, such as can be de-

scribed in terms of a mean velocity, and an intensity of turbulence. Once the arc has failed to reignite, of course, displacement of the bubble may follow very quickly.

Conclusion 3 seems to offer a plausible explanation for the well-known inconsistency of many types of fluid circuit breakers when tested near their interrupting limit.

Theory of the Brush-Shifting A-C Motor—I

J. G. CLARKE
ASSOCIATE AIEE

Synopsis: This is the first of a series of papers explaining the theory and principles of operation of the brush-shifting a-c motor. Operation of the machine, either as a motor or a generator, is explained on the basis of the superposition of currents. The theory of the primary current loci is developed for both high-speed and low-speed adjustments. A method of determining the primary current loci from no-load measurements is presented. Experimental data have shown the theory to be valid.

IN general, a-c polyphase motors are less adaptable to speed adjustment than are d-c motors. However, by use of a combination of regulating winding, a commutator, and brush-shifting facilities, a polyphase induction motor can be so constructed as to provide speed adjustment similar to that obtainable on a d-c shunt motor. These motors are essentially three winding motors. The primary winding placed on the rotor is supplied from the line through slip rings. The stator winding (see figure 1) is a phase wound secondary. The third winding is placed on the rotor and is provided with a commutator. Voltages collected from this commutator are inserted into the secondary circuit. Speed adjustment is obtained by changing the settings of the brushes. These a-c machines have speed-torque characteristics similar to those of the d-c shunt motor. Because of this similarity, they are sometimes called a-c shunt motors.

The authors have presented a simple explanation of the theory of this a-c adjustable speed, commutator type of motor based on ordinary induction motor theory which they have checked and found to be fundamentally sound. This explanation employs an extension of the application of the induction motor circle diagram theory. This new theory, meritorious because of its simplicity, is most helpful in explaining some of the motor characteristics such as power factor correction, design requisites for certain speed ranges, generator action, and its use for regenerative braking. The accuracies of the results obtained by this theory indicate that it may be found useful industrially as well as academically.

The Motor

The speed of an ordinary induction motor can be changed by inserting into the secondary element a voltage of slip frequency, provided this voltage is in such a phase position that it forces a power component of current into the secondary (that is, this current produced in the secondary is not maximum when the flux surrounding the secondary conductors is zero). In the particular motor described here, this current (see figure 1) is obtained from an adjusting winding placed on the rotor. This adjusting winding is provided with a commutator and provision is made for collecting voltage from it by use of adjustable brushes which are connected to the secondary. The secondary is located on the stator and the primary on the rotor. The brushes are mechanically coupled so that they are spaced at the same distance for each secondary phase winding, thereby insuring equal voltages conducted to each secondary phase. When the brushes of each secondary phase are adjusted so that they are in contact with the same commutator segment, the secondary is short-circuited, and no voltage is supplied from the adjusting winding. Under these conditions, the motor behaves like an ordinary induction motor, and the adjusting winding is in no way operative. The speed can be reduced by separating the brushes in a given direction so the voltage collected from the brushes causes a component of secondary current which produces a negative torque. The machine can be operated above synchronism by shifting the brushes, that is, interchanging their positions (*a*) to (*b*), and (*b*) to (*a*)—figure 2, so that the voltage collected by these brushes is in such a direction as to force a current through the secondary which will produce positive torque. The motor can be reversed by reversing two of the leads supplying the primary.

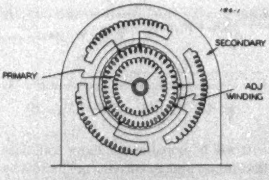

Figure 1. The motor circuit

The Theory of Speed Adjustment

Speed adjustment cannot be obtained merely by inserting a voltage into the secondary from the brushes unless this voltage is in such a direction as to cause a current that is torque producing. A voltage collected by the brushes even though large in magnitude may produce little or no change in speed if the current that it produces in the secondary conductors is in quadrature with the flux surrounding these secondary conductors. Such a condition will materially change the power factor of the motor without appreciable change of speed. Since it is possible to change both the magnitude and direction of this voltage collected from the adjusting winding, there is an infinite number of different brush settings that may give the same speed adjustment. However, there is but one setting of the brushes that will provide a given speed at a given power factor for a given load. Since all of these variables are interdependent, it is desirable that some form of explanation which shows their relation be presented. To show these relations, a specific brush setting will be chosen and the operation of the motor

explained for this setting. An understanding of the operation for this one brush setting will be most helpful in determining the conditions for other possible settings.

Operation Below Synchronous Speed

Let us assume that it is desired to operate this motor at half synchronous speed. This can be accomplished by spacing the brushes so that the voltage E_{11} induced in the adjusting winding between the brushes (*a*) and (*b*), figure 2, is exactly 180 degrees out of phase with the voltage E_2 induced in the secondary due to slippage of the secondary with respect to the flux. The separation of the brushes should be sufficient to make E_{11} equal to half the standstill value of E_2 in order to obtain a no-load speed equal to half synchronous speed. In figure 2 and in all following references this induced voltage due to slippage will be designated as E_2 and the current that it forces through the secondary and the adjusting winding included between the brushes will be designated as I_2. The voltage induced in the adjusting winding between the brushes will be referred to as E_{11}, and the current that it causes to flow is designated as I_{11}.

The total current flowing in the secondary for any condition of operation is the sum of the currents I_2 and I_{11}. The magnitude of this total current can be best understood by dealing with these two components separately to determine their nature, and then adding them to obtain the total current.

Assuming that the flux is constant for constant impressed primary voltage, the voltage per turn in the adjusting winding will be constant regardless of the speed. Therefore, for any given brush setting, E_{11} will be constant (independent of slip). The frequency of E_{11} changes with slip and at all times is the slip frequency of the motor. The voltage E_2 induced in the stator by this constant flux is directly proportional to the slip and is of slip frequency. Therefore E_2 and E_{11} are always voltages of the same frequency. The current I_2 which is caused by the voltage E_2 is impeded by the stator phase resistance R_2, the stator phase reactance X_2, the resistance of the adjusting winding R_{AW}, and the reactance of the adjusting winding X_{AW}. The current I_{11} is limited by the same impedance that limits I_2. Expressions for these currents are:

$$I_2 = \frac{E_2}{\sqrt{(R_2+R_{AW})^2+(X_2+X_{AW})^2}} \tag{1}$$

$$I_{11} = \frac{E_{11}}{\sqrt{(R_2+R_{AW})^2+(X_2+X_{AW})^2}} \tag{2}$$

Letting

E_2 at standstill be ${}_{ss}E_2$
X_2 at standstill be ${}_{ss}X_2$
X_{AW} at standstill be ${}_{ss}X_{AW}$
S = per cent slip

Then

$$I_2 = \frac{{}_{ss}E_2S}{\sqrt{(R_2+R_{AW})^2+({}_{ss}X_2S+{}_{ss}X_{AW}S)^2}} \tag{3}$$

or

$$I_2 = \frac{{}_{ss}E_2}{\sqrt{\frac{(R_2+R_{AW})^2}{S^2}+({}_{ss}X_2+{}_{ss}X_{AW})^2}} \tag{4}$$

$$I_{11} = \frac{E_{11}}{\sqrt{(R_2+R_{AW})^2+({}_{ss}X_2S+{}_{ss}X_{AW}S)^2}} \tag{5}$$

It will be noted in the above equations that the secondary currents are limited by an impedance made up among other things of the reactance ${}_{ss}X_{AW}S$. This is the reactance offered to currents of slip frequency, and the voltages that are produced by this reactance and the secondary currents ($I_{2ss}X_{AW}S$ and $I_{11ss}X_{AW}S$) are independent of the primary supply frequency. At synchronous speed these voltages become zero and the secondary current is limited by the resistances only. This is on the basis of course that all the flux cuts all three windings.

On the basis of the equations 4 and 5, the vector diagram of the secondary circuit including its portion of the auxiliary winding can be constructed as in figure 3. From equation 4, it is evident that the extremity of the vector I_2 has a locus following the path of a semicircle as in an ordinary induction motor. Equation 5 shows that the vector I_{11} also has a circle locus. From equations 1 and 2, it is evident that the impedance offered to I_2 and I_{11} are the same, and therefore, these currents must lag their respective voltages by the same angle, therefore the angle $\theta_2 = \theta_{11}$. The maximum value of I_2 (diameter of circle) is equal to $\frac{{}_{ss}E_2}{{}_{ss}X_2+{}_{ss}X_{AW}}$ and the maximum value of I_{11} is obtained at 100 per cent power factor of the secondary or at synchronous speed and is equal to $\frac{E_{11}}{R_2+R_{AW}}$.

The current I_2 produces torque in the direction of rotation (positive) while the current I_{11} produces a negative torque.

The positive torque $= K\phi I_2 \cos\theta_2$
The negative torque $= K\phi I_{11} \cos\theta_{11}$

In these equations, ϕ = flux. It is assumed to be constant in magnitude, and that all of it cuts the primary winding,

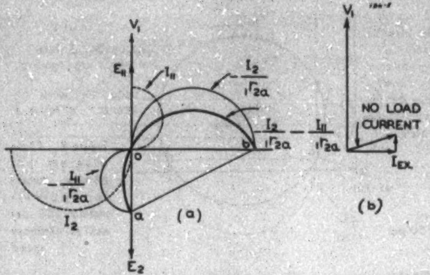

Figure 5. Currents

(*a*)—Of secondary reflected to the primary

(*b*)—Taken by primary at no load

the adjusting winding, and the stator winding. Since $\theta_2=\theta_{11}$ for this brush setting, the total torque is—

$$T=K\phi(I_2-I_{11})\cos\theta_2 \qquad (6)$$

For a condition of no load (zero developed torque) I_2 and I_{11} are equal and opposite. Or in other words, the rotor must slip sufficiently to make I_2 increase to a value equal to and opposite to I_{11}. Since the brushes are so spaced that E_{11} is one-half E_2 at standstill, E_2 and E_{11} will be equal and opposite at 50 per cent slip, and the no-load speed will be one-half synchronous speed. If slippage is increased by further reduction of speed (loading), I_2 becomes larger, I_{11} smaller, and a positive torque will result. This is motor action and it occurs at a speed less than no-load speed. If now the machine is driven at some speed slightly above its no-load speed, I_2 will be reduced, and I_{11} increased. Under these conditions, the torque produced by I_{11} becomes higher than that produced by I_2 and the total torque is negative. This condition results in generator action. Thus with this machine generator action can be obtained at any speed within its speed range. These principles are illustrated further in figure 4.

Primary current for different conditions of load can be determined from the secondary currents and from the no-load exciting current in a manner similar to that used for the ordinary two-element induction motor. However, special consideration must be given to the turn ratios for the particular motor. Any turn ratio involving the adjusting winding is a function of speed adjustment (brush setting).

The effect of the secondary currents on the current taken by the primary can be explained from the diagram of figure 5*a*. This diagram shows the locus of the components of secondary current I_2 and I_{11} when E_2 and E_{11} are 180 degrees out of phase and the machine is adjusted at a no-load speed corresponding to approximately 50 per cent slip or one-half synchronous speed. The current I_2 flowing in the stator and through the adjusting winding will cause a current to flow in the primary of sufficient magnitude and direction so as to neutralize the flux produced by I_2. This component of the primary current is $\frac{-I_2}{{}_1r_{2a}}$ where ${}_1r_{2a}$ is equal to the ratio of the number of turns on the primary to the difference of the number of turns on the stator, and the number of turns in the adjusting winding that are placed in the secondary circuit by this particular brush setting, or ${}_1r_{2a}=\frac{N_1}{N_{2a}}$. The current I_2 passing through both the stator and the adjusting winding will produce fluxes in these two windings that are opposite in direction with respect to the primary circuit. The component of the primary current that neutralizes the magnetizing effect of I_2 is therefore a vector that has its extremity defined by the path of the circle $\frac{-I_2}{{}_1r_{2a}}$ shown in figure 5*a*.

Likewise, the current I_{11} will cause a component in the primary current which by the same reasoning as above must be 180 degrees out of phase with I_{11}. The magnitude of this primary component is $\frac{-I_{11}}{{}_1r_{2a}}$, and is defined by a current locus which is the path of another circle—figure 5*a*. If these two components of the primary current are now added vectorially, their sum would be $\frac{-I_2}{{}_1r_{2a}}-\frac{I_{11}}{{}_1r_{2a}}$ and the locus of this resulting current could be represented by another circle the diameter of which is $ab=\sqrt{\overline{oa}^2+\overline{ob}^2}$. When the machine is running at no load the sum of these currents becomes zero. If the machine is operated at synchronous speed, the sum of these currents becomes *oa*. A resultant current below the line *bo* indicates generator action—a resultant current above this line, which has a component in the direction of the primary impressed voltage V_1, indicates motor action. The locus of motor currents and generator currents is defined by this circle *boa*. This circle however does not show the total primary current because of no-load losses and the requirements of an exciting current. Figure 5*b* shows the no-load loss and exciting components of primary current with respect to the impressed voltage V_1. The total primary current I_1 can now be obtained by adding the current defined by the circle locus *aob* of figure 5*a* to the no-load current shown in figure 5*b*. This construction results in a diagram, figure 6, which shows the relation of the primary current to the primary impressed voltage for different load conditions when brushes are set to reduce speed, to approximately 50 per cent of synchronous speed (${}_{ss}E_2=2E_{11}$).

Operation Above Synchronous Speed

The speed of this motor can be raised to a value above synchronous speed by

reversing the potential E_{11} applied to the stator winding. This is done by transposing brush positions, i.e., in figure 2, brush *b* would be moved to the position of brush *a*, and brush *a* to the position of brush *b*. By reversing the direction of the voltage E_{11} applied to the stator, the current I_{11} will have a positive torque and tend to drive the motor at a high speed. For speeds above synchronous E_2 also reverses (since the flux reverses its direction of rotation relative to the stator), and I_2 now produces a negative torque tending to bring the motor back to synchronous speed. The vector diagram for this condition is shown in figure 7. It will be noted that both voltages are reversed with respect to the primary voltage V_1 from their position of figure 5*a*.

The current I_{11} flowing in the adjusting winding and stator will cause a primary current component $\frac{-I_{11}}{{}_1r_{2a}}$ where ${}_1r_{2a}$ is the ratio of the number of turns on the primary to the sum of the number on the stator and the adjusting winding between brushes. For this speed adjustment, the fluxes produced by the stator and adjusting winding are in the same direction with respect to the primary. Likewise, I_2 will cause a primary current component $-\frac{I_2}{{}_1r_{2a}}$.

When these currents of figure 7 are reflected to the primary circuit, with due regard to turn ratios, they provide a portion of the total primary current vector diagram shown in figure 8*a*. The total primary current resulting from the secondary currents in the adjusting winding, and the stator winding is the vector sum of the currents defined by the two current loci. Their vector sum is another current locus ${}_{2a}I_1$ which is defined by another circle *oac*. The complete vector diagram for the primary supply can now be obtained by superimposing the vectors of figure 8*a* on those of the no-load diagram of figure 8*b*. This complete diagram is shown in figure 9.

It will be noted that the resultant locus of the primary current of figure 9 is moved toward the vector V_1 from its position shown in figure 6. With this high-speed adjustment and with brushes set to make E_{11} opposite to E_2, the power factor of the motor can be made quite high at large loads, and the maximum power that the motor can develop is much higher than that of the low-speed adjustment described previously. This is indicated by the maximum power component of the primary current of figure 9 as compared with that of figure 6.

Experimental Check on Theory

In order to more fully verify the theory of the motor advanced thus far, an experimental check was made on one of these motors to see how closely the current taken under load followed the current predicted by the current loci circles. The machine, a General Electric B.T.A., 600–1800 rpm, 6 pole, 60 cycles, 4.1–12.5 horsepower, was first adjusted so that its no-load speed was 600 rpm (one-half synchronous speed). The brushes were set by opening the secondary connections at the brushes and adjusting the brushes so that the voltage across them, E_{11}, was one-half the voltage E_2 across the open-circuited stator coil at standstill. This gives only one of the necessary brush adjustments. The other adjustment for phase position of E_{11} is obtained by keeping the brushes fixed with respect to each other and moving them together on the surface of the commutator until the voltage E_{11} was 180 degrees out of phase with E_2. With this setting, the stator coils can now be reconnected to the brushes for operation at one-half synchronous speed for no load.

The current taken with this brush setting for different values of motor output is indicated by the encircled points in figure 10. The circle which should pass through these points can be located by measuring the no-load primary current (*po*), and the primary blocked rotor current (*pb*).

By erecting a perpendicular to the line *ob* one diameter of the current circle locus is established. If the line *ob* is extended to the point *f* so that $\frac{of}{bf}=\frac{{}_{so}E_2}{E_{11}}$ the point *f* will fall on the locus of $\frac{-I_2}{{}_1r_{2a}}$. From points *o* and *f* the circle $\frac{I_2}{{}_1r_{2a}}$ can be constructed and consequently the point *e* is located. A perpendicular to *oe* will be another diameter to the primary current circle locus. The intersection of the two diameters establishes the center of the circle. The accuracy of this circle diagram is revealed by the proximity of the points obtained experimentally with the current circle locus *cob*.

To check the theory for higher speeds, the brush positions were interchanged so that the voltage E_{11} between them at standstill on open circuit was one-half the voltage E_2 induced in the open-circuited secondary and in phase with it. This adjustment provided a no-load speed of 1,800 rpm (150 per cent synchronous speed).

A current locus circle can be determined in the same manner as for the lower speed adjustment. This current locus along with the experimental points obtained by loading are shown for this speed adjustment (150 per cent synchronous speed) in figure 11. The circle locus predicted on the basis of no-load and short-circuit current provides a fair determination of the current characteristics of the machine. While there appears to be some divergence between this circle and the true current locus indicated by the curve through the encircled points, the actual differences as would be indicated on instruments as to power factor, magnitude of currents, etc., are small. of figure 11 which displays this difference on a standard machine also, with proper interpretation reveals that the theory thus far developed is sound. However, the differences between the theoretical circle and the experimental current locus can be explained on the basis of the primary leakage reactance.

Effects of Primary Leakage Reactance

In a motor such as described here provision is made for two windings on the rotor and one on the stator. The necessary spacing of the primary winding with respect to the stator introduces primary leakage reactance. This reactance produces a voltage 90 electrical degrees ahead of the current in the primary which subtracts from the applied voltage in such a way that the voltage induced in the primary by the mutual flux (mutual to primary and to the stator) lags the applied voltage. Consequently at speeds above synchronism, this mutual flux must introduce a voltage in the stator winding which is ahead of the voltage that would be present if there were 100 per cent coupling between the two windings. The angle of lead of this voltage in the stator is exactly equal to the angle of lag between the total primary back electromotive force and the back electromotive force produced by the mutual flux. This lead in stator voltage will cause the circle with diameter *oe* of figure 11 to swing about the point *o* in the direction of the rotation of the vectors with increase in load on the motor. Since the leakage between the two rotor windings (primary and adjusting winding) is small, there is little shift of the circle *of* due to primary leakage fluxes.

It has been found experimentally that the true primary current locus represented by the points shown in figure 11 can be predicted from no-load data of three sets of measurements taken on the motor. These determinations are, as follows:

1. The no-load input current and watts.
2. The standstill input current and watts at reduced voltage.
3. The input current and watts on reduced voltage with the machine running.

The first and second determinations above are made in the customary manner. The third determination can be made by applying a reduced voltage to the primary sufficient to rotate the machine at no load at a speed somewhere intermediate between its no-load speed and standstill. A speed of approximately 50 per cent of no-load speed provides fair accuracy in construction of the circle.

From the data of the three above items, it is possible to calculate the current, power factor, etc., for normal voltage. From these three values of primary current and their respective power factors, it is possible to construct the circle locus of the primary current previously developed, and also to locate it in accordance with the shift created by the primary leakage reactance. This more accurate determination of the primary current locus is shown in figure 12. The current *PO* is the no-load current, the current *PS* is the standstill current for normal voltage determined from data taken at reduced voltage, and the current *PR* is a current that the motor would take when running on normal voltage under some load. This current *PR* is determined for a running condition at reduced voltage.

The center of the circle of figure 12 can be found by erecting perpendiculars to the chords *RS* and *OR*. Once this center *C* is located a circle can be drawn through the

F. ZWEIG
ENROLLED STUDENT AIEE

J. G. CLARKE
ASSOCIATE AIEE

Synopsis: In the preceding paper[1] of this series, a simple theory underlying the circle diagram of the brush-shifting a-c motor was presented. It is the purpose of this paper to advance this theory, and to show how it can be used to determine such quantities as efficiency, current, torque, and speed for different conditions of operation. The procedures outlined and explained have been checked experimentally, and found to be accurate for both high-speed and low-speed adjustments.

THERE is an infinite number of possible brush settings that can be made on the brush-shifting a-c motor. It is possible to move the brushes so as to change the magnitude or phase position, or both magnitude and phase position of the voltage collected from the commutator. Such movements can be used to change speed, or the power factor or both speed and power factor. Any change in brush setting will materially change the circle diagram proportions. Therefore, any circle diagram for this motor is useful only in determining the characteristics of the machine for one brush setting. However, an understanding of the use of the circle diagram for a particular setting of the brushes will be most helpful in obtaining a general understanding of the operation of the machine for other settings. Therefore, the diagrams used for a basis of explanation will be those corresponding to the settings described in Part I, i.e., when the machine is operated at 50 per cent of synchronous speed with the two secondary voltages in direct opposition, and when operated at 150 per cent of synchronous speed with the two secondary voltages in direct opposition. Characteristic circle diagrams for these brush settings are shown in the upper portion of figure 3.

Determination of the Circle Diagram

The circle diagram can be determined from three sets of readings taken at no load. These determinations are as follows:

(*a*). No-load input current and watts at normal voltage

(*b*). The standstill input current and watts at reduced voltage

(*c*). The no-load input current and watts at reduced voltage with the machine running at some speed between no-load speed and standstill

From the data of these three sets of readings, the circle diagram of figure 1 can be constructed. This diagram is characteristic of the machine for speed adjustments below synchronous speed. The line *po* shows the no-load current and its direction with respect to the impressed voltage V_1. It is obtained from determination (*a*) above. The standstill current I_{ss} for normal applied voltage is represented in magnitude and direction by the line *pb*. It is obtained from determination (*b*). A third point, *x*, on the circle is located from determination (*c*). This point is obtained from conversions made on data taken with reduced voltage. Having the points, *o*, *x*, and *b* on the circle, it is possible by erecting perpendiculars to two of its chords to locate the center *r*. Using *or* as a radius, the circle locus of the primary current *oxb* can be located.

Determination of Characteristics From the Circle Diagram

Having established the currents *po* and *pb* in magnitude and direction with respect to the vector V_1, the lines *pe* and

---

points *O*, *R*, and *S* which very accurately predicts the primary current locus with respect to the impressed voltage. The accuracy of this method of determining this locus is evident from the proximity of the locus of the points determining the true locus obtained experimentally.

The theory presented here has been verified through experimental data. It is assumed to be fundamentally sound. An advancement of this theory for use in the analysis of the losses, slip, efficiencies, and power factor correction has been made, but falls without the scope of this paper. These advancements will be presented in a later publication.

List of Symbols

E_2—Voltage induced in one phase of stator

E_{11}—Voltage generated in adjusting winding between brushes supplying one phase of stator

I_2—Current flowing in stator and adjusting winding resulting from the voltage E_2

${}_{ss}X_{AW}$—Adjusting winding reactance at standstill

θ_2—Angle of lag between E_2 and I_2 electrical degrees

θ_{11}—Angle of lag between E_{11} and I_{11} electrical degrees

θ—Angle of lag or lead between primary phase voltage and primary phase current

ϕ—Total flux produced by primary windings

K—Torque constant of the motor

T—Torque developed (synchronous watts)

${}_1r_{2a}$—Ratio of the number of turns on the primary to the effective number of turns on the secondary and adjusting winding

N_1—Number of primary turns

N_{2a}—Effective number of secondary turns per phase included in stator and adjusting winding circuit. This quantity is a function of speed adjustment as well as power factor adjustment

V_1—Primary impressed voltage per phase

I_1—Primary current per phase

I_{ex}—Exciting current in primary circuit per phase

${}_{2a}I_1$—Component of primary current flowing as a result of the currents in stator and adjusting winding

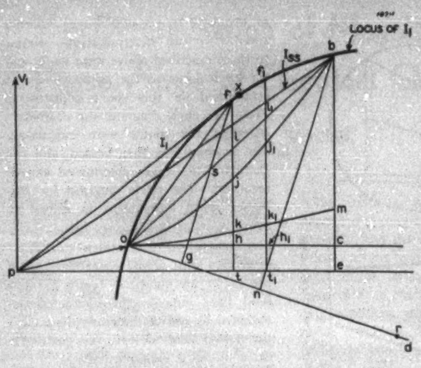

Figure 1. The circle diagram for the low-speed adjustment

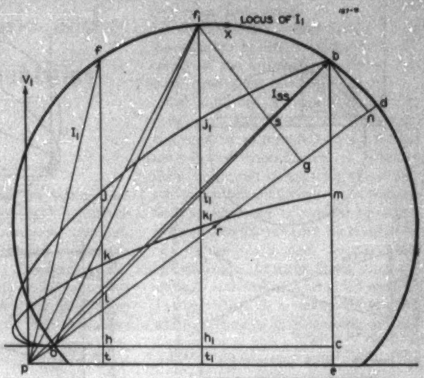

Figure 2. The circle diagram for the high-speed adjustment

oc can now be constructed perpendicular to V_1 and the line *be* perpendicular to *pe*. The power supplied to the motor at standstill per phase is the current *be* multiplied by the voltage V_1. The current *ce* multiplied by the voltage V_1 is the per phase iron loss of the rotor, the friction and windage losses, and a small amount of iron loss in the stator. By measurements of primary resistance, the primary copper losses per phase can be calculated for the normal short-circuit current. This loss is represented by the current *cm*. The loss in the adjusting winding and in the stator per phase for standstill conditions is $(bm)V_1$.

The copper losses can be estimated for any value of primary current in a manner somewhat similiar to that normally used with the ordinary induction motor. Thus for an input current of *pf*, it is assumed that the no-load current is one component and the loss associated with it, $(ce)V_1$, is constant regardless of the magnitude of the load. The other component of the primary current *pf* is *of*, and the losses associated with this component can be determined by the relations—

$$\text{Loss for current } of = \text{loss for } ob\left(\frac{\overline{of}}{\overline{ob}}\right)^2$$

Another method of determining the copper loss for the current *pf* is to erect a perpendicular *bn* from the point *b* to the diameter of the circle, and another perpendicular *fg* to the same diameter. The copper losses associated with the current *of* are expressed as—

$$\text{Loss for current } of = \frac{(bc)(sg)}{bn}V_1 \text{ watts per phase}$$

Having determined the total loss for this current *of* in terms of a current in phase with the voltage, this loss caused by the current *of* can now be laid off on a line *fh* drawn from *f* perpendicular to *oc*. In figure 1, it is labeled *hj*. Similarly, the total copper losses can be determined for other values of input current. Thus for an input current of pf_1, the total copper loss is h_1j_1. By successive determinations of losses, the curve *ojb* can be constructed to show the change in copper losses with different values of input current. If each of the distances *jh*, j_1h_1 are divided so that $\frac{jk}{kh}=\frac{j_1k_1}{k_1h_1}=\frac{bm}{mc}$ a new curve *okm* can be constructed so that the distance h_1k_1 shows the variation in primary copper loss, and k_1j_1 shows the variation in secondary (adjusting winding and stator) copper losses for different values of primary current.

The variables for the motor can now be determined for any value of input current I_1.

(1). Input $=(ft)V_1$ watts per phase
(2). Output $=(jf)V_1$ watts per phase
(3). Iron loss, friction, and windage $=(ht)V_1$ watts per phase
(4). Primary copper loss $=(hk)V_1$ watts per phase
(5). Copper losses of stator and adjusting winding $=(jk)V_1$ watts per phase
(6). Efficiency $=\left(\frac{jf}{ft}\right)$ 100 per cent
(7). Slip $=\left(\frac{jk}{kf}\right)$ 100 per cent of no-load speed
(8). Speed $=\left(1-\frac{jk}{kf}\right)$ times the no-load speed
(9). Torque $=(kf)V_1$ synchronous watts per phase

For speeds above synchronism, a similar treatment can be applied. Figure 2 shows the circle diagram for the same motor as that of figure 1, except the speed is adjusted to approximately 150 per cent of synchronous speed. The standstill current I_{ss} for normal voltage is much larger, and maximum power output much greater. The circle is located from the three sets of no-load determinations described previously. The essential difference of this diagram as compared with that of figure 1 is the shape of the curves showing copper losses for different primary currents. The system of notations on figure 1 has been maintained in figure 2, so that the explanation of the use of figure 1 will suffice for the explanation of the use of figure 2.

Experimental Check on the Theories of the Circle Diagram

In order to check the validity of the theory thus far developed, tests were made on a General Electric B.T.A. 550–1,650-rpm, 4.17–12.5-horsepower, 6-pole, 60-cycle brush-shifting motor. The brushes were set by making the brush voltage E_{11} at standstill equal approximately one-half the voltage ${}_{ss}E_2$ in the stator coil to which they were connected. Care was taken to make these voltages opposite in direction. With this setting, the no-load tests described above under the headings (*a*), (*b*), and (*c*) were made to determine the circle locus of the primary current. The machine was then loaded and readings of speed, torque, current, watts, and volts were obtained for different values of output. The primary resistance was determined by measuring the resistance of the pri-

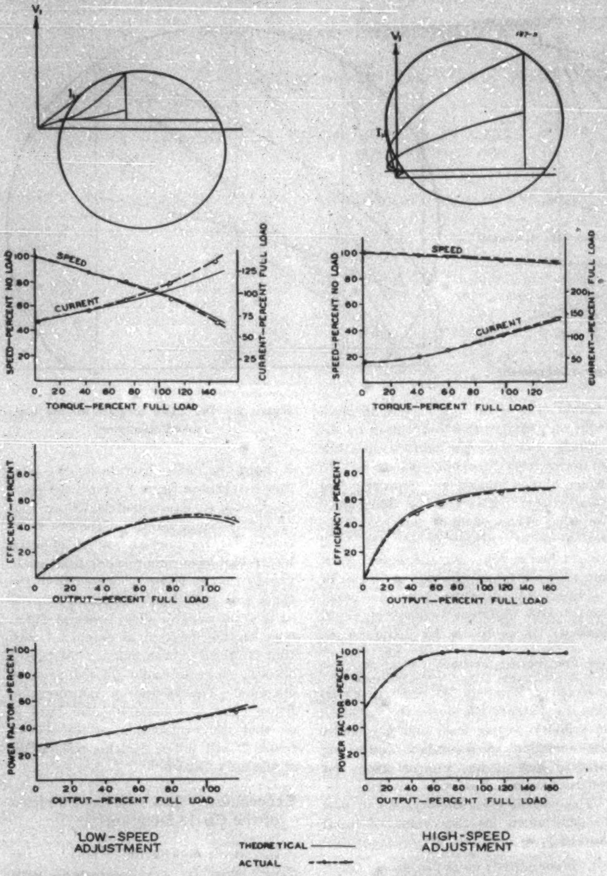

Figure 3. Comparison of the theoretical characteristics taken from the circle diagram with the actual characteristics obtained by tests for no-load speeds, approximately 50 per cent of synchronous speed, and 150 per cent synchronous speed

mary winding with direct current. From the no-load tests the circle diagram of the machine was constructed, and the characteristics determined from its proportions. The theoretical diagram for this machine with this low-speed setting is shown in figure 1.

A second experimental check was made with the brushes set to provide a speed of approximately 150 per cent of the synchronous speed. This can be done by making the voltage E_{11} across the brushes at standstill equal to one-half the stator voltage $_{ss}E_2$ of the stator coil to which they are normally connected. In addition to this, these two voltages should be in time phase with each other at standstill to provide proper running speed. No-load determinations similar to those described above were made and the circle locus of the primary current established for this speed adjustment. From this circle diagram, the characteristics of the motor were calculated. The machine was then loaded, and the characteristics again determined experimentally. The circle diagram for this higher speed adjustment is shown in figure 2.

A comparison of the theoretical characteristics with actual characteristics of the motor are shown in figure 3. The solid lines indicate the characteristics obtained by use of the circle diagram—the dotted lines indicate the characteristics obtained experimentally.

Conclusions

The proximity of the curves obtained from measurements made on the circle diagram to those obtained by the load test, indicates that the circle diagram developed and explained in this series of papers can be used to determine the operating characteristics of the brush-shifting motor accurately. While the circle diagrams of the motor have been shown and checked for only two speed adjustments, the explanation of the theory of the use of these diagrams can be applied to other diagrams constructed for different speed adjustment on the motor. A large portion of the theory thus far developed is directly applicable to the explanation of conditions within the motor when it is adjusted for power factor corrections; however, this is beyond the scope of this paper, and will be presented in another publication.

The Determination of Magnitude and Phase Angle of Electrical Quantities

ERIC A. WALKER
MEMBER AIEE

Synopsis: Although the three-voltmeter method for measuring the relative magnitude and phase angle of two voltages or currents is well known, the use of vacuum tube voltmeters, which draw negligible amounts of energy from the circuit, permits the use of the method for purposes which previously have not been considered. A further improvement of the scheme by balancing out one component of either voltage or current adds to the accuracy of the results. The method is considered for two purposes, namely: the measurement of the capacitance and power factor of imperfect condensers, and the measurement of the ratio and phase angle of current transformers.

Purpose

THERE are two well-known methods by which the constants of an unknown impedance may be determined. They are by balancing networks or bridges, of which there are many types,[1] or by the use of a wattmeter, voltmeter, and ammeter. Both methods are used successfully for a wide variety of impedances, even to the determination of the capacitance and power factor of cables and high-voltage bushings.[2,3,4]

There are also two principal methods by which the relative magnitudes of two voltages or two currents and the phase angle between them may be determined. They are by the use of an a-c potentiometer of the Tinsley-Drysdale type,[5] or by use of a modified bridge method.[6]

A third method for determining the magnitude and angle of an impedance, voltage, or current is known as the three-voltage, or three-voltmeter method.[7] The method has been known for a long time but it has been less widely used than the methods mentioned previously because of its supposed inaccuracy. For determining voltages, the method consists of measuring the two unknowns separately and then measuring their sum or difference. The scheme is inaccurate if the circuit on which the voltages are impressed is composed of high-impedance elements, and the instruments draw sufficient current to disturb the vector relations in the circuit. However the development of vacuum tube voltmeters and amplifiers, which draw little or no power from the circuit and thus have negligible effect on circuit conditions, makes a re-examination of the method desirable.

This re-examination is made more important because there are cases when an unavoidable variation in the circuit parameters occurs during the test, making it very difficult to obtain a balance on a bridge. Furthermore there are cases, such as in the testing of current transformers, when it becomes necessary to design circuit elements to carry large currents. Then inductances become undesirable because of the magnetic fields which are produced and capacitors for large currents soon become unwieldy and expensive.

The Modified Three-Voltmeter Method

If one has two alternating voltages of the same frequency it is possible to determine their magnitudes and the phase angle between them by three-voltage measurements and a graphical or trigonometrical analysis. Figure 1*a* shows two voltages across two impedances on which three-voltage measurements can be made because of the common connection. In figure 1*b* E_1 is drawn along the real axis. Then arcs equal in length to E_2 and E_3 are drawn from the ends of E_1 and the phase angle θ is determined. If the measuring instruments do not disturb the distribution of voltage in the circuit the accuracy is limited only by the accuracy of the instruments and the personal error of the operator.

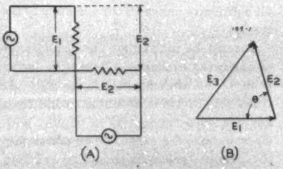

Figure 1. The three-voltage method for determining the magnitude and phase angle of two voltages

One difficulty is present if the two voltages E_1 and E_2 are nearly in phase and equal in magnitude for then a small error in the determination of either of them may result in recording three voltages which will not form a closed triangle. Such an error can be avoided by a procedure which balances out one component of a voltage in a manner which will now be explained. In figure 2*a* the circuit of figure 1*a* is shown with an added element. To the voltage E_2 a voltage E_2' is added which is variable in magnitude and 180 degrees out of phase with E_1. (This requires a transformer with exactly 180 degrees phase shift, a limitation which will be discussed later in this article.) Figure 2*b* shows the voltage relations in this circuit. It is evident that when the voltage E_3 is a minimum the phase angle between E_1 and E_2 is:

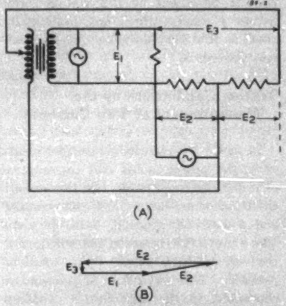

Figure 2. The method of balancing out one component of a voltage vector to determine the phase angle

$$\theta = \sin^{-1}\frac{E_3}{E_2}$$

Therefore it is only necessary to determine these two voltages in order to find the phase angle. For very small angles a further approximation can be made:

$$\theta = \sin^{-1}\frac{E_3}{E_2} \approx \tan^{-1}\frac{E_3}{E_2}$$

$$\theta(\text{radians}) \approx \frac{E_3}{E_2}$$

These formulas are useful in studying the defect angle of condensers or of current transformers.

Paper 41-89, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE North Eastern District meeting Rochester, N. Y., April 30–May 2, 1941. Manuscript submitted November 19, 1940; made available for preprinting March 11, 1941.

(A)

(B)

Figure 3. Circuit and vector relations for determining the defect angle of an imperfect condenser

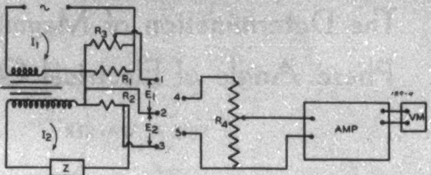

Figure 4. Circuit for determining the phase angle of a current transformer

Although this method has been discussed for voltages it is obvious that the vector relationship is applicable also to currents. Either the currents themselves can be measured or the voltage drop across resistors which are sufficiently small so that they do not appreciably affect the circuit.

Testing Condensers by the Measurement of Two Currents

In figure 3 a circuit is shown for measuring the power factor and capacitance of imperfect condensers. In this circuit the transformer has a 5,000-volt winding and a 100-volt winding, both shielded. The phase angle between the voltages of the two windings should be as small as possible. The imperfect condenser is connected to the high-voltage winding and a leading current flows through the detector *D* as is shown in figure 3*a*. This current leads the voltage by an angle θ and the condenser is said to have a defect angle δ, where $\delta = 90$ degrees $-\theta$. The defect angle is determined by closing switch *S* and varying the air condenser *C* until a minimum current is reached. This is

$$I_D = I_1 + I_2$$

Then

$$\delta = \sin^{-1}\frac{I_D}{I_2} \quad \delta(\text{radians}) \approx \frac{I_D}{I_2}$$

Typical readings made on a high-voltage bushing are as follows:

$I_2 = 1{,}120$ microamperes at 5 kv and 60 cycles per second

$I_D = 60$ microamperes at 5 kv and 60 cycles per second

$$= \frac{60}{1{,}120} = 0.0535 \text{ radian}$$

$$C_x = \frac{1{,}120 \cdot 10^{-6}}{5{,}000 \cdot 377} = 594 \text{ micromicrofarads}$$

(approximately)

These measurements were checked on a Schering bridge. Although power factors which are too low to measure by this method can still be determined by a Schering bridge, this system showed one important advantage in the measurement of the power factor of wet oil. With the bridge the power factor of the oil changed too rapidly for a successful reading to be made, but with this circuit the variation could be followed without much difficulty because as I_d changes there is no appreciable variation in the out-of-phase component of I_2 and the power factor is approximately proportional to I_d.

This circuit is also useful in making tests where corona may be present at higher voltages. The circuit can be balanced at a low voltage and as the voltage is increased the current I_d should increase in direct proportion. Any sudden increase indicates a departure from linearity in the condenser being tested.

It is important to notice that the calibration of the air condenser C_S does not enter into the result. The only requirements are that the voltages E_1 and E_2 must be in phase and that the impedance of the detector be sufficiently low so that the phase angle is not affected. Both of these effects can be checked by placing an air condenser at C_x with a known resistance in series to give a known power factor. For a detector it is possible to use a rectifier type microammeter or, for lower impedance, a noninductive resistance with an amplifier and vacuum tube voltmeter can be used. A filter in the amplifier circuit to suppress all harmonics increases the accuracy of the results.

It must be noted that the capacitance of balancing condenser C_S must be larger than C_x by the ratio of E_1 to E_2. At times this makes it desirable to add fixed low-loss mica condensers in parallel with C_S to extend the range. The power factor of these condensers should be less than one per cent of the condenser being tested.

This circuit has been found very useful for measuring the defect angles of cables, bushings, and other impedances having defect angles from 0.005 to 0.1 radian. It is desirable to shield the device to keep stray currents out of the meter.

Application to Current-Transformer Testing

At present two methods are used for testing current transformers: the mutual inductance bridge method, and the "Silsbee" or comparative method. The first requires one or two calibrated mutual inductances, and the second requires a transformer similar to the one being tested but with a known ratio and phase angle. An arrangement requiring neither of these is shown in figure 4. In this circuit R_1 and R_2 are decade boxes, and *Z* is the burden with which it is desired to test the transformer. The resistance R_3 should be sufficiently large so that it diverts a negligible amount of current from R_1. A ratio of 10,000 to 1 or higher is usually used. The vacuum tube voltmeter consists of a three-stage, resistance-coupled, amplifier with 70 decibels gain and an input resistance of about one megohm. Readings are taken on a rectifier-type microammeter in the output circuit of the amplifier. With the method described here, a calibration of the amplifier-voltmeter combination is not necessary. Greater accuracy can be attained by inserting a 60-cycle band pass filter in the amplifier to eliminate any harmonic voltages from the voltmeter reading.

The method of making the test is as follows: the input terminals of the meter (terminals 4 and 5) are connected to points 2 and 3, and tap of R_4 is adjusted until full scale is indicated on the output meter. This value of R_4 is recorded as R_4'. Next the meter input is connected to points 1 and 2, and with R_4 unchanged the tap on R_3 is adjusted until full-scale deflection is obtained on the voltmeter. Call this setting on R_3, R_3'. Then:

$$E_{23} = E_{12} \qquad E_{12} = I_1 R_1 \frac{R_3'}{R_3} \qquad E_{23} = I_2 R$$

$$\text{Transformer ratio} = \frac{I_1}{I_2} = \frac{R_2}{R_1} \cdot \frac{R_3}{R_3'}$$

The next step is to connect the input terminals of the meter to points 1 and 3. This reading should be much less than the previous ones. If it is not the polarity of the secondary winding must be reversed. The tap on R_4 is now changed until full-scale deflection is obtained once more. This setting on R_4 is recorded as R_4''. One now has:

$$E_{12} \cdot \frac{R_4'}{R_4} = E_{13} \frac{R_4''}{R_4}$$

$$\theta = \sin^{-1} \frac{R_4'}{R_4''}$$

$$\theta(\text{radians}) = \frac{R_4'}{R_4''} \text{ (approximately)}$$

A typical set of readings are:

Rated primary current—50 amperes
Rated secondary current—5.0 amperes (nominal)
$R_1 = 0.01$ ohm $\quad R_2 = 0.10$ ohm
$R_3 = 10{,}000$ ohms $\quad R_4 = 10{,}000$ ohms
$R_3' = 999.0$ ohms $\quad R_4'' = 10{,}000$ ohms
$R_4' = 14.0$ ohms

$$\text{Ratio} = \frac{0.1}{0.01} \times \frac{10{,}000}{999.0} = 1.0010$$

$$\theta(\text{radians}) = \frac{14.0}{10{,}000} = 0.0014 \text{ radian}$$

$$\theta = 28.8 \text{ seconds}$$

It is important to understand that the general method is not limited to the two cases cited. These are two illustrative examples where the method has proved of value and other examples can be found. The measurement of the voltage relations along an artificial transmission line or the measurement of the phase relations in resonant circuits might be mentioned.

Ampere-Squared-Second Recorder

T. A. RICH
ASSOCIATE AIEE

Synopsis: A device is described which records the ampere-squared seconds in an electrical impulse of less than 0.5-second duration. A number of these have been used in resistance-welding applications to monitor the electrical variables and have contributed greatly to the uniformity of welds. The problem of indicating $^1/_{60}$-second impulses at the rate of 100 a minute with the same device that will correctly integrate a half-second impulse has been solved by the use of a moving element with an infinitely long natural period, combined with a supplementary circuit which returns the element to the starting position in a fraction of a second.

Introduction

IN resistance welding, it is necessary to control many variables to get optimum results. The control of the surface conditions of the material being welded, the size and shape of the electrodes, and the pressure between electrodes are mechanical and metallurgical problems. The control of the energy used in welding is a combined electrical, mechanical, and metallurgical problem. The electrical energy which produces the heat is a function of the square of the current, the time of application, and the resistance. The resistance at the weld will depend upon mechanical and metallurgical conditions which themselves must be subjected to careful control. It is logical then to measure as an electrical entity only those conditions which are responsive to electrical control, namely current and time or $\int i^2dt$. The usual welding circuit is highly reactive and the resistance of the material being welded has but little effect on the current, and therefore the ampere-squared seconds are not greatly influenced by variables which should be controlled by nonelectrical means.

An ampere-squared-second recorder should:

1. Give a record for each weld.
2. Operate over the range of currents and time used in resistance-welding operations, and be adjustable to indicate 100 per cent for any specified value of $\int i^2dt$.
3. Not limit the speed of welding.
4. Give an alarm when specified limits are exceeded.
5. Stand extreme overloads.

With such a device, the supervisor can adjust the sensitivity of the recorder to read 100 per cent for the correct electrical conditions for a given welding job. The operator then works in the usual way, and the device makes a record for each weld. If the electrical conditions change appreciably for any subsequent weld, an alarm is given, and, in some applications, the welding control is automatically locked.

The currents and times used in resistance-welding operations vary over a wide range, but by the use of transformers, any desired fraction of the current and therefore of the ampere-squared seconds in the circuit can be applied to the ampere-squared-second recorder. The most usual range of time is from $^1/_{60}$ to $^1/_2$ second, or from 1 to 30 cycles with a 60-cycle-per-second source. The rate of welding may be as high as 100 per minute on welds of a few cycles duration.

A conventional a-c ammeter can be used to indicate ampere-squared seconds if the duration of the impulse is short in comparison with the natural period of the instrument. If the moving element starts from rest, the maximum throw is directly proportional to ampere-squared seconds. Before the next impulse can be applied, the instrument must have come to rest again. For accurate work, the natural period should be ten or more times as long as the length of the longest impulse to be measured. When the longest impulse is 0.5 second, this would require a natural period of 5 seconds and the rate of welding on the shorter impulses would be less than 12 per minute.

Principles of a Suitable Mechanism

The arrangement finally developed is somewhat similar in operation to the Grassot fluxmeter. Instead of a mechanism for producing kinetic energy from the impulse and then converting to potential energy, as is done in ballistic measurements, a mechanism is used which produces an angular velocity proportional to the current squared which is maintained for the duration of the impulse.

Paper 41-88, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941. Manuscript submitted February 28, 1941; made available for preprinting April 1, 1941.

T. A. RICH is an electrical engineer with the general engineering laboratory of General Electric Company, Schenectady, N. Y.

Figure 1. Moving element for ampere-squared-second recorder

The moving element consists of two separate iron-vane ammeter elements, an eddy-current damping vane, and a pointer, all on the same shaft, as in figure 1. One ammeter element produces clockwise rotation due to the impulse and the other counter-clockwise rotation from a separate source to return the element to the starting position. The deflecting element is at the bottom and the return element at the top in figure 1. The element can also be seen in position in figure 2.

If there were no physical limitations, the element would be made with no inertia, no spring torque, and no friction. Under these idealized conditions and with the element at rest, the torque applied when one ammeter element is energized is proportional to the current squared. The moving element instantly takes on a velocity such that the damping torque is equal to the applied torque. Since the damping torque is directly proportional to the angular velocity, it follows that angular velocity is proportional to the current squared. Under this condition of no inertia, the element will stop instantly when the impulse stops. The angular displacement then is proportional to the integral of i^2dt.

When inertia is present, the element will neither start nor stop instantly. In the appendix, it is shown that the angular displacement from a point of rest to a final rest position is independent of the inertia. In the derivation, friction is neglected because in a practical design the actuating torques will be large in comparison with friction torques.

The equations show that the deflection is proportional to $\int i^2dt$ when: (1) the electrical torque is proportional to the square of the current and independent of the angular position, and (2) the damping is proportional to velocity. In the recorder described, the damping is proportional to velocity, but neither of the other conditions are strictly met. The overall results, however, are such as to obtain substantially linear response with $\int i^2dt$.

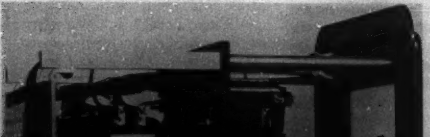

Figure 2. Side view of ampere-squared-second recorder with case off

Auxiliary Devices

The basic element described needs the addition of a recording and alarm mechanism and a device to control the sequence of events to make a complete instrument. (See figure 3.)

A. Method of Recording

A record of the maximum deflection of the pointer for each impulse is recorded on a strip chart. The chart drive is so arranged that the paper moves at a uniform speed as long as the welds are not spaced more than a few seconds apart.

A relay-operated print bar brings the pointer sharply against the strip chart (which is backed up by an inked roller ribbon) after the pointer comes to rest. This makes a short line on the back of the paper. The paper used is thin and the record shows through as a series of dots, one for each weld. The distance of the dot from the starting position is directly proportional to ampere-squared seconds. Once the record is printed, the other ammeter element is energized for a fixed time to return the element to the starting position.

The printing bar is carried by the Z-shaped member in figure 2. The printing bar is of metal except for an insulated

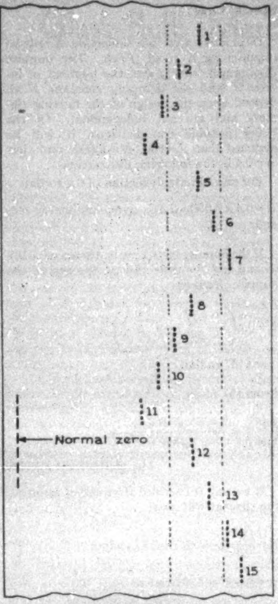

Figure 4. Tracing of an actual record from the weld recorder

Each of the darker dots represents one weld. The allowable limits are represented by the two parallel rows of light dots at the right. Groups 1 through 7 were made with 3 cycles current—the current changed as follows:

1—Current normal
2—Current reduced 5 per cent
3—Current reduced 10 per cent
4—Current reduced 15 per cent
5—Current normal
6—Current increased 5 per cent
7—Current increased 10 per cent

Groups 8 through 21 were made with current and voltage to the welder held constant and timing changed:

8—10 cycles
9— 9 cycles
10— 8 cycles
11— 7 cycles
12—10 cycles
13—11 cycles
14—12 cycles
15—13 cycles

insert at the point corresponding to 100 per cent deflection. An alarm is sounded if the pointer is not beneath the insulated insert when printing occurs. The length of the insert is determined by the tolerance allowed in $\int i^2 dt$. Usual practice permits a variation of ±15 per cent in the ampere-squared seconds. An example of the type of record is shown in figure 4.

B. Sequencing Unit

The "brain" of the device is a unit which knows when to print the maximum deflection, when to energize the return element, and how long it must be energized to come to rest in the starting position.

The sequence of events is:

1. The impulse occurs and the pointer starts to move.
2. There is a waiting period while the pointer comes to rest.
3. The printer operates.
4. The moving element is returned to the starting position.
5. The device is made ready for the next impulse.

The waiting period must start when the impulse ends. The length of the waiting period depends upon the velocity at the end of the impulse, the moment of inertia of the system, the amount of damping, and the accuracy required.

The greatest velocity will be attained for the shortest weld and if the waiting period is sufficient for correct indication then, it will be more than adequate for any longer weld. The relationships used in determining the waiting time are shown in the appendix. On a one-cycle weld, with the recorder in figure 3, the pointer deflects approximately 25 per cent in the sixtieth of a second the impulse lasts and then coasts to nearly 100 per cent in the next tenth of a second. With the same recorder, it will deflect about 95 per cent of the final deflection during a 30-cycle weld, and in the next tenth of a second be substantially 100 per cent of final deflection. With the element used, a tenth-second wait was found adequate.

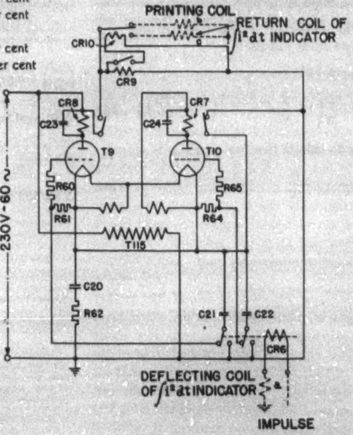

Figure 5 (right). Schematic diagram of sequence unit

Since there is practically no control torque on the moving element, it will remain in any position it is placed. The zero position is determined by a stop, but a slight unbalance or shock might move the element in time. To provide a definite zero position, a small amount of magnetic material is attached to the damping vane. The damping magnets attract this material and hold the pointer against the stop. Only a small deflection is required to carry the magnetic material out of the field of the damping magnets.

Only a short time can be allowed for the return of the pointer, so it is necessary to accelerate it rapidly. On the other hand, if it hits the zero stop with high velocity, it will bounce and the return element will need to be energized until it comes to rest. The return element was designed to have high torque when the pointer was near full scale and to have the torque fall off rapidly as the element approached zero position. The return of the pointer from any scale position to rest at the zero position can be accomplished in 0.15 second.

A schematic diagram of the unit which controls the sequence of events is shown in figure 5. Under stand-by conditions, vacuum tube *T*-10 is conducting and relay *CR*-7 is energized. Tube *T*-9 is blocked by capacitor *C*-20 (which is charged to approximately 300 volts by current passed by *T*-9). The grids of both tubes are at filament potential. When an impulse is received, *CR*-6 is energized which connects the grid bias capacitors *C*-21 and *C*-22 in parallel with *C*-20. The grid bias capacitors then share the charge with the blocking capacitor and some current is passed by *T*-9 to again block itself, but this is not enough to operate *CR*-8. No visible change occurs except that *CR*-6 pulls in and stays in during the impulse. When the impulse ends, *CR*-6 drops out, connecting the charged bias capacitors across each grid. Both tubes are then well beyond cutoff and *CR*-7 drops out. This short-circuits the blocking capacitor *C*-20, but *T*-9 cannot yet pass current because of the high negative grid voltage. The charge on *C*-21 leaks off and 0.1 second after *CR*-6 opened, *T*-9 becomes conducting pulling in *CR*-8, which energizes the printing relay and *CR*-9. When *CR*-9 pulls in, it operates *CR*-10 which transfers power from the print coil to the return coil of the recorder. About 0.15 second after *CR*-8 operated (or 0.25 second after *CR*-6 dropped out) the bias of *T*-10 has leaked off enough to conduct and pull in *CR*-7. This removes the short circuit from the blocking capacitor *C*-20 and it charges up and stops the flow of current through *T*-9 and *CR*-8. Then *CR*-8, *CR*-9, and *CR*-10 drop out and the circuit is again ready for another sequence.

Conclusion

A considerable number of these recorders have been put in service in the last three years. In spite of the apparent complexity, the high-speed operation, and the rough usage they receive, their performance has been satisfactory. While the recorder is particularly designed for resistance-welding applications, the combination utilized represents a new measuring tool that may be valuable in other fields.

Appendix

Assume system starts at rest when $t=0$ (time) and $\theta=0$ (angular deflection). The impulse starts at $t=0$ and lasts for a second (producing a uniform torque) of D dyne-centimeter seconds. The torque is $\left(\frac{D}{a}\right)$ dyne-centimeter. When the system moves there will be a counter torque due to inertia $\left(J\frac{d^2\theta}{dt^2}\right)$ and one due to the damping magnets $\left(N\frac{d\theta}{dt}\right)$.

$$J\frac{d^2\theta}{dt^2}+N\frac{d\theta}{dt}=\frac{D}{a} \tag{1}$$

Let

$$N\frac{d\theta}{dt}-\frac{D}{a}=p$$

$$\frac{J}{N}\frac{dp}{dt}+p=0 \tag{2}$$

$$\frac{J}{N}\ln\frac{pa}{D}+t=0 \tag{3}$$

$$p=\frac{D}{a}e^{\frac{Nt}{J}}=\frac{D}{a}-N\frac{d\theta}{dt} \tag{4}$$

$$-\frac{J}{N}e^{\frac{-Nt}{J}}=t-\frac{Na\theta}{D}+c \tag{5}$$

When

$t=0 \quad \theta=0$

$$\theta=\frac{D}{Na}t-\frac{JD}{N^2a}\left(1-e^{-\frac{Nt}{J}}\right) \tag{6}$$

$$\frac{d\theta}{dt}=\frac{D}{Na}\left(1-e^{-\frac{Nt}{J}}\right) \tag{7}$$

At the end of the impulse $t=a$, $\theta=\theta_1$, $\frac{d\theta}{dt}=\left(\frac{d\theta}{dt}\right)_1$

$$\theta_1=\frac{D}{N}\left(1-\frac{J}{Na}\left(1-e^{-\frac{Na}{J}}\right)\right) \tag{8}$$

$$\left(\frac{d\theta}{dt}\right)_1=\frac{D}{Na}\left(1-e^{-\frac{Na}{J}}\right) \tag{9}$$

The torque due to current ceases at this point and letting

t' = time after impulse stops
θ' = angle traversed after impulse stops

$$J\frac{d^2\theta'}{dt'^2}+N\frac{d\theta'}{dt'}=0 \tag{10}$$

As before let

$$\frac{d\theta'}{dt'}=p'$$

$$\ln\frac{p'}{p_0'}+\frac{N}{J}t'=0 \tag{11}$$

$$\theta'=\frac{J}{N}\left(\frac{d\theta}{dt}\right)_1\left(1-e^{-\frac{Nt'}{J}}\right) \tag{12}$$

The deflection at any time (t) after the *start* of the impulse =

$$\Delta=\theta_1+\theta'$$

$$\Delta=\frac{D}{N}\left(1-\frac{J}{Na}e^{-\frac{N(t-a)}{J}}\left(1-e^{-\frac{Na}{J}}\right)\right) \tag{13}$$

at an infinite time

$$\Delta=\Delta_\infty=\frac{D}{N} \tag{14}$$

Special Case

In practice a certain deflection Δ will be required for a given $\int i^2dt$. The impulse D obtained from $\int i^2dt$, the moment of inertia J, and the damping constant N all depend upon the design of the moving element and are not independent. Of the many possible combinations, it will be assumed that $J=150$, $N=6{,}000$, and that $\Delta=0.4$ in the following illustration.

For an ultimate deflection of 0.4 radian

$D=0.4\times 6{,}000=2{,}400$ dyne-centimeter seconds

If the impulse lasts 1 cycle, then $a=0.0167$ second and the deflection at the end of the impulse (from 8)

$$\theta_1=0.4\left(1-\frac{60}{40}\left(1-e^{-\frac{40}{60}}\right)\right)$$

$$=0.107 \text{ radian}$$

From (9)

$$\left(\frac{d\theta}{dt}\right)_1=\frac{2{,}400\times 60\times 0.487}{6{,}000}=$$

11.7 radians per second

If we wait 0.1 second after end of impulse, the element will coast

$$\theta'=\frac{11.7}{40}(1-e^{-4})=0.287 \text{ radian}$$

$$\Delta=\theta_1+\theta'=0.394 \text{ radian}$$

$$\Delta_\infty=0.400 \text{ radian}$$

For the one-cycle case a change of 25 per cent decrease in the assumed wait of 0.1 second would make 3 per cent difference in overshoot or 2.2 per cent change in indicated value. An increase of 25 per cent will cause less change.

At 30 cycles, $a=0.5$ second

$$\theta_1=0.4\left(1-\frac{2}{40}\left(1-e^{-20}\right)\right)$$

$$=0.380 \text{ radian}$$

$$\left(\frac{d\theta}{dt}\right)_1=0.8 \text{ radian}$$

Waiting 0.1 second, the element will coast

$$\theta'=\frac{0.8\times 0.982}{40}=0.0196 \text{ radian}$$

$$\Delta=0.399 \text{ radian}$$

Glass-Bulb Mercury-Arc Rectifiers for Traction Service

CHARLES E. WOOLGAR
MEMBER AIEE

Synopsis: The paper gives a general survey of the ability of glass bulb mercury-arc rectifiers to satisfactorily meet the stringent requirements of traction service. The subject matter is arranged on the assumption that engineers of the United States and Canada are not familiar with the use of this type of equipment for traction work, and the author has approached the subject from the point of view of an engineer considering the merits of different types of conversion equipment.

Major features pertaining directly to glass bulbs are discussed such as plant capacity, maintenance, efficiency, robustness, etc., but no attempt is made to include wider problems common to mercury-arc rectifiers as a class, namely frequency changing, inversion, harmonics, etc.

Introduction

THE first type of rectifier installed in England (1923) for traction service was a glass bulb mercury-arc rectifier, and installations of this type are widely used for traction service in Great Britain and countries served by British manufacturers. Glass bulb installations exceeding 5,000 kw in capacity are in service operating for the most part within the 500 to 1,600-volt range most commonly employed for D.C. traction. On the London Passenger Transport Board system alone approximately 80,000 kw of glass bulb rectifier plant (distributed among more than 50 substations) is installed for operating trams and trolley-busses. For railway electrification, glass bulb rectifiers are equally serviceable and widely used. Typical examples are London, Midland and Scottish Railway (recently, electrification of the Euston-Watford line required 17 substations each approximately 2,500 kw), Bombay, Baroda and Central India Railway, and the New Zealand Government Railways. In 1938, against world wide competition, one glass bulb rectifier manufacturer received 15,000 kw of a 19,800-kw contract for traction rectifiers in South America. Typical Canadian traction installations are: British Columbia Electric Railways (2–330 kw, 1–660 kw), City of Edmonton 1–700 kw), and Britannia Mining and Smelting Company (1–330 kw).

Approximate over-all dimensions of a 1,000-kw, 550-volt D.C. rectifier, excluding transformer, would be 23 ft long by 4 ft deep by 9 ft high.

The above information indicates that there is nothing new in using glass bulb rectifiers for traction service.

Plant Capacity

The current output of a single glass bulb being limited, engineers unfamiliar with the equipment question the advisability of operating a number of bulbs in parallel. They know that to obtain 2,000 kw at 800 volts D.C., i.e., 2,500 amp, it would neither be economical nor practicable to operate numerous rotary convertors in parallel, and naturally do not immediately appreciate that this arrangement can be utilized with glass bulbs to the greatest advantage. Eight or ten glass bulbs would be paralleled, depending on the size of bulb used.

Arc voltage drop being proportional to the arc current a number of parallel arc paths minimizes the voltage drop and thereby increases plant efficiency. For example, if a single tank rectifier has an arc drop of 20 volts at 500 amp and 25 volts at 3,000 amp, then a 3,000-amp equipment comprising 6–500 amp units would effect a saving of about 15 kw in arc drop. Allowing for extra fan and exciter losses, this may represent an efficiency gain of 1%.[1,4]

It is well known that an arc tends to concentrate within a small space on the anode and steel tank rectifier manufacturers have had to resort to baffles and shields to obtain more even distribution. Arc concentration overheats the anode and gives rise to conditions liable to cause backfire. It has been found that the best way to obtain effective increase in anode area, is not by increasing the size of anodes, but by increasing their number. For the 2,000-kw traction rectifier mentioned above, the steel tank rectifier would probably be equipped with 12 anodes, whereas 8 six-arm glass bulbs would have 48 anodes, thereby having an enormous effective anode area to ensure avoidance of hot spots.[1]

Should inspection or maintenance be necessary on a bulb cubicle, that cubicle can be readily cut out of service without disturbing operation of the remaining cubicles. Thus in the above case, the seven bulbs would share full load between them, slightly overloaded, until the other bulb was restored to service. With other conversion equipment such maintenance would probably entail shutting down the entire unit.

In Great Britain, general development of steel tank rectifiers is in the direction of air-cooled pumpless units whose present outputs are between 250 and 750 amp, and the chief engineer of one manufacturer of both steel tank and glass bulb rectifiers, states that the general trend of application is in the direction of operating convenient-sized units in parallel rather than employing large single units with numerous anodes.[1] The advantages of the multi-unit construction used by glass bulb manufacturers, are now becoming more generally recognized.

Characteristics of Conversion Equipment

The engineer must examine a number of important factors before reaching a decision on conversion equipment. The more important of these factors are discussed below and the degree to which glass bulb rectifiers meet desired characteristics is considered.

1. INITIAL COST

(*a*) *Equipment.* The cost per kw varies considerably, but steel tank, steel bulb, and glass bulb rectifiers are all competitive and show to advantage over rotating equipment.

(*b*) *Buildings.* Glass bulb cubicles can, in general, be arranged in equal or less floor space than single tank rectifiers, and as they have no auxiliaries such as water cooling pipes, pumps, recoolers, blower motors, or special starting equipment, building costs are less than for other conversion equipment.

(*c*) *Installation.* The costly foundations required for rotating equipment are not necessary for rectifiers, and the uniform weight distribution of glass bulb

330 kw, 550 volts d-c, double bulb unit complete with high speed circuit breaker panel, installed in British Columbia

cubicles can be sustained by a much lighter floor than that required by other types of rectifiers.

Since each cubicle is a self-contained rectifier unit with all auxiliaries (excluding main and auxiliary transformer) the installation, testing, and setting to work is much simpler than that required by more complicated types of conversion apparatus. This represents a considerable saving in initial cost.

2. MAINTENANCE

(*a*) *Attention Required.* In common with other types of conversion equipment, glass bulb substations can be unattended, operating automatically or by remote control. No special attention is required.

(*b*) *Inspection.* Bulb transparency is of considerable practical value to operating engineers since by merely opening the cubicle doors it is immediately apparent whether the rectifier is firing properly. If required, individual bulbs can readily be removed from service and complete inspection carried out without interrupting supply to the remaining bulbs.

(*c*) *Sources of Trouble.* The sources of trouble of rotating equipment are well known and need not be discussed here, but it is advisable to draw some comparison between steel tank and glass bulb rectifiers in this respect.

In most steel tank rectifiers the great majority of breakdowns occur in auxiliary equipment, not in the rectifiers. On one large traction system, the records of 16 rectifiers over a period of 19 months showed maintenance carried out as follows: control gear—45.5%, vacuum pumps—31%, water system—21%, rectifiers—2.5%. Percentages refer to the number of failures. On those occasions when steel tanks must be opened and baked out, the expense involved due to outage of plant and cost of power for bake-out may be considerable.[2]

In glass bulb rectifiers connectors passing through the bulb wall have the same coefficient of expansion as the glass, thereby ensuring no leakage through the seals. The bulb itself is not porous and therefore perfect conditions for a permanent vacuum obtain. No pumping is required. Cooling is provided by a vertical-motor-driven fan, placed directly under the bulb. Ignition may be very simply accomplished with a dipping electrode attracted to a small, external electromagnet operated from the exciter transformer. The only moving parts are the fan and a small contactor which operates when starting. No other auxiliaries are required.

Glass bulb rectifiers, having a minimum of auxiliaries, require negligible maintenance.[6]

(*d*) *Bulb Life.* The life of a glass bulb is indefinite, as no wear occurs. Records show many bulbs in service 15 years without developing trouble. Possibly the best commentary is the fact that glass bulbs of reliable manufacture can be insured at $4^1/_2\%$ per annum to cover a period of 10 years. Experience has shown however, that maintenance and replacement costs are too small to justify even this small premium. For a 2,000-kw traction rectifier of 8 bulbs, insurance at the above rate costs approximately 20 cents per kw per annum.

3. EFFICIENCY

The advantages of lower arc drop and resulting increased efficiency consequent upon multi-unit construction were briefly discussed under "Plant Capacity."

At the load factors encountered in traction service, the all-day efficiency of rectifiers shows to advantage over rotating equipment,[3] due largely to the relatively flat rectifier efficiency curve from $^1/_4$–$^5/_4$ load. Typical efficiencies (in per cent) for glass bulb traction rectifiers are:

D-C Voltage	Load				
	$^1/_4$	$^2/_4$	$^3/_4$	$^4/_4$	$^5/_4$
600	93.75	94.2	94.1	94	93.8
1,200	95.6	96	95.9	95.6	95
1.500	96	96.5	96.5	96.2	95.6

4. POWER FACTOR

The average power factor for glass bulb rectifiers is fairly flat over the normal operating range, varying from 0.90–0.94 approximately between one quarter load and full load.

5. VOLTAGE REGULATION

Glass bulbs, like steel tank rectifiers have a drooping voltage characteristic, the regulation being approximately 5%. Compounding can be effected by grid control, voltage regulator, or by means discussed in other papers.[5]

6. OVERLOADS

(*a*) *Standard Ratings.* For glass bulbs standard overload ratings for traction service are:

25% overload	2 hours
50% overload	$^1/_2$ hour

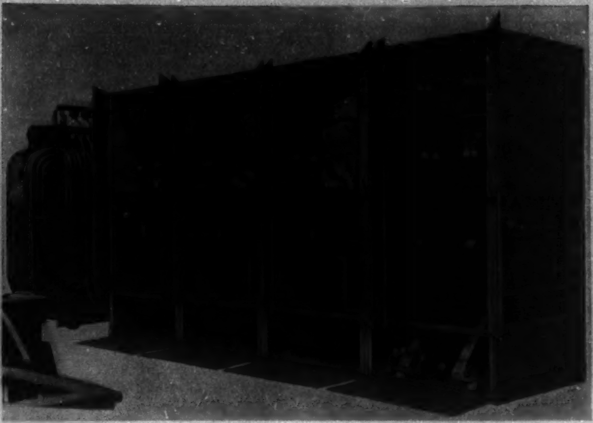

Figure 2. Railway traction rectifier

One of a set of six banks, each 600 kw, 650 volts d-c, with d-c smoothing equipment, England

100% overload	5 minutes
200% overload	momentary peaks

(*b*) *Non-Standard Ratings.* It is a simple matter to supply a glass bulb rectifier with any overload capacity required by simply installing the right number and type of bulb units with a suitable rectifier transformer. Actually each traction installation must be considered on its own merits and equipment supplied to meet particular load requirements.

(*c*) *Short Circuits.* Glass bulbs handle severe track short circuits without distress. Experience indicates that glass bulbs are less affected by short circuits than other types of conversion equipment. One engineer with wide operating experience of both rotating and static equipment confirmed that rectifiers are less sensitive than rotary converters and added that in his experience steel tanks were liable to backfire on track short circuits occurring within a half-mile of the substation but glass bulbs were not affected. The author does not intend this to represent a general condition but merely the experience of a particular engineer. It is of interest, however, that in 1938 another engineer stated "we employ a certain number of these (steel tank rectifiers) for traction purposes, but some of them have not approached the glass bulb type in respect of reliability."[1]

Multi-unit construction with its resultant low current density per anode, large effective anode area, and conditions of permanent vacuum contributes largely to stability under severe overload and short circuit conditions.

7. STABILITY AND ROBUSTNESS

(*a*) *A-C System Disturbances.* It is well known that rectifiers are insensitive to fluctuations of voltage or frequency in the A.C. network and in this respect ensure an absolute minimum interruption of traction supply not obtainable with rotary converters.[2,3]

(*b*) *Starting Time.* Ability to restart instantaneously after shut-down due to system disturbance, or to start up from cold in an emergency and to at once take on full load is of major importance. Glass bulb operation is largely independent of temperature and rectifiers of this type will start up and deliver full load current without delay. Pre-heating is not required except possibly in cold climates where the substation air temperature remains below freezing point for lengthy periods. Room temperatures from 4°C–40°C ensure immediate starting and stable operation.

(*c*) *Robustness.* Objections to glass bulbs are raised on the grounds of fragility and sensitivity to continued vibration or concussion. This has proved to be a fallacy. The bulbs are made of a special quartz type of glass and when handled with reasonable care breakages rarely occur. They are completely enclosed in individual sheet steel or expanded metal cubicles, and if anything, less liable to damage than the exposed commutators, brushes, relays, gauges, etc. of other types of conversion equipment.

The bulbs are secured firmly but flexibly in a suitable cradle and anode and cathode connections made through flexible copper conductors. Free from rigid connections of any type the bulbs are unaffected by continued vibration. Installations operating satisfactorily near gun testing locations at Woolwich Arsenal, underground in mines and subjected to blasting shocks, or in regions subject to earth tremors are ample evidence of their insensitivity to concussion.

Figure 3. Railway traction rectifier

3,600 kw, 1,200 volts d-c, installation comprising three 1,200-kw banks. One of two similar substations, England

8. Paralleling and Extensions

(*a*) *Paralleling Similar Units.* Each bulb unit of a multi-unit installation is adjusted at the factory for correct operation. In the two largest glass bulb substations in the world, 6,500 kw and 7,000 kw at 500 volts D.C. (industrial load) automatic, unattended, and remote-controlled, there are 44 and 40 bulbs respectively operating in parallel.

(*b*) *Paralleling Dissimilar Equipment.* Glass bulb units can and do operate in parallel with rotating equipment or steel tank rectifiers of equal or unequal capacities. Correct load sharing is arranged to suit plant conditions. To avoid considerable complication in grid control gear and high speed relays, it is desirable to arrange the rotating plant with a slight drooping voltage characteristic.

(*c*) *Extensions.* Glass bulb rectifier plant can be extended at any time and to any desired extent by adding the appropriate number of bulb units. This entails a considerable saving in capital cost as extensions to most conversion equipment necessitate installing units of large capacity.

Conclusions

Glass bulb rectifiers are suitable for traction service and in some respects show to advantage over other types of conversion equipment, particularly so in the multi-unit construction, lack of troublesome auxiliaries, high overall efficiency, reliability, negligible maintenance costs, and flexibility.

A New Mercury Rheostatic Element for Regulation and Control

K. A. OPLINGER
MEMBER AIEE

Introduction

In many regulating and control systems, the primary or actuating stimulus is available only at a low power level and must be amplified to obtain sufficient power output for the various control functions. This requirement, along with the increased use of automatic controls during the past few years has resulted in many industrial applications which require a simple, reliable power amplifier. Electronic tubes and special designs of rotating machines have been used for amplification where a continuous type of control is required, but in most applications it is difficult to justify the use of tubes or rotating amplifiers.

Contact Controls

Contact relays are often used for amplifying power in control circuits of the "on" and "off" type. For continuous control, a single pair of vibrating contacts makes a very simple amplifier. If the contacts are operated in a hovering position, their effective resistance varies with contact pressure and large changes in resistance, which will give large current changes, can be obtained with extremely small variations in pressure. The ratio between the change in resistance and the change in pressure is a measure of the contact amplification. It is possible to obtain very high values of amplification in this manner and to adjust this amplification by changing the amount of contact vibration. A practical application of the contact amplifier to speed regulators was described in a previous paper.[1] The power output of such an amplifier is, of course, limited by the current interrupting capacity of the contacts.

Rheostatic Control

Another simple device for controlling larger amounts of power is the rheostat. By using a large number of steps it is possible to secure practically continuous control. Novel rheostatic control members have been built which require very little force and movement to operate a large number of contacts.[2] In designing a rheostatic control, the following requirements are of importance in most regulating and control systems:

1. The power required to operate the rheostat should be small since the actuating stimulus is usually at a low power level.
2. Hysteresis resulting from frictional and magnetic forces should be small.
3. The inertia of moving parts and their displacement should be low to permit quick response.
4. The contacts should require no maintenance.

The above requirements become more difficult to meet as the output power of the rheostatic control is increased. By making use of the well-known advantages of the mercury switch, a new form of multicontact mercury rheostat has been developed to meet all of the above requirements and at the same time handle relatively large amounts of power. For convenience in describing this new device it has been called a "Mercurystat".

Design of Mercurystat

The contact element of the Mercurystat contains a large number of mercury switches so arranged that they can be operated by a small force and travel. The construction is shown by the schematic drawing, figure 1. A 40-step Mercurystat with its electromagnetic driver is shown in figure 2. Referring to these two figures, small flat terminals

Paper 41-98, recommended by the AIEE committee on industrial power applications, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted March 26, 1941; made available for preprinting April 15, 1941.

K. A. Oplinger is with the research laboratories of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The author wishes to acknowledge the assistance received from his associates in the laboratories and engineering departments and particularly the many helpful suggestions made by C. R. Hanna. The special speed control application described in this paper was made in co-operation with C. W. Drake and J. Z. Linsenmeyer. The speed matcher application was made in co-operation with C. E. Valentine and R. A. Geiselman.

[1] For all numbered references, see list at end of paper.

each having a central hole, are assembled as shown with an insulating spacer between each pair of terminals. Stainless steel bellows with a plug to reduce the volume of mercury, are attached to the bottom of the terminal assembly. Displacement of the bellows raises and lowers a central mercury column which shorts out, or cuts in, sections of an external resistor connected to the ends of the terminals. A gas space is provided at the top of the terminal assembly to prevent an appreciable change in pressure from the slight changes in volume caused by the bellows displacement. The entire assembly, consisting of bellows, terminals, insulators, and gas space, is hermetically sealed by a special process so that the interior of the Mercurystat can be pumped out and charged with an arc-reducing gas such as hydrogen. It is then sealed off from the atmosphere to eliminate all contact maintenance.

Because of the large ratio between the area of the bellows and the area of the mercury column, only a small displacement of the bellows is required to short out all terminals. In the 40-step Mercurystat shown in figure 2, the terminal assembly is about two inches high but only a few thousandths of an inch displacement of the bellows is required to short out all steps.

Power Capacity

The power capacity of the Mercurystat is fixed by the current interrupting capacity of the contacts and by the internal losses of a given design. The contact duty in a rheostat of this type is much less severe than in the ordinary mercury switch operated at line voltage. The large number of steps reduces the voltage across steps so that relatively high currents can be handled. For example, a small 40-step Mercurystat as shown in figure 2 can easily control six kilowatts. Life tests made with a unit this size operating in a 220-volt d-c circuit and varying the current from 12 amperes minimum to 30 amperes maximum showed practically no sign of contact wear after 5,000,000 cycles of operation.

At higher currents, the internal losses of the above design were greater than could be dissipated with a reasonable temperature rise. These losses result from the resistance of the terminals and the mercury column and from the contact drop between the mercury and the terminals. Greater power capacity can of course be obtained by increasing the cross section of the terminals and the mercury column. This will reduce the resistance of these parts and at the same time give a larger assembly capable of radiating more heat. The contact drop tends to remain constant as in the case of carbon brushes on slip rings and is in the order of about one-half volt for currents up to 100 amperes.

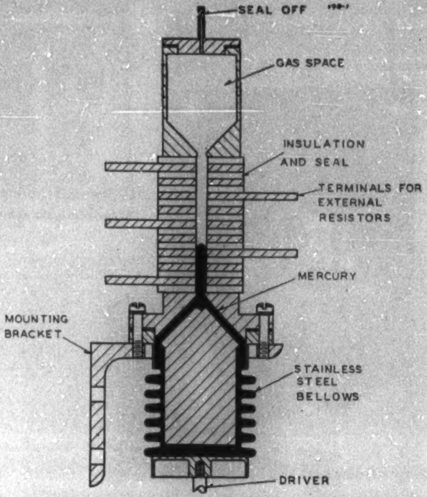

Figure 1. Schematic diagram of Mercurystat

Design of Driver

In some applications the bellows of the Mercurystat can be operated directly by a lever or cam which is a part of the control system. In other cases it is desirable to have an electromagnetic driver so the Mercurystat can respond to electrical stimuli. A driver for this purpose should be free of friction and magnetic hysteresis and should have some reference standard such as a spring force for its calibration. Such a driving element is shown in figure 2. The driving arm is mounted on cross springs to provide a frictionless pivot. An insulating turnbuckle is used to connect the bellows to this arm. A calibrating spring is attached to one end of the driving arm while an iron armature is mounted on the other end. The armature travels in a magnetic circuit having a constant air gap and a laminated iron core. By proper armature shaping the negative magnetic stiffness of the driver can be made to match the positive stiffness of the Mercurystat and calibrating spring so that very small changes in coil current will cause the driver to move through a wide range. Typical response curves of a Mercurystat and driver are shown in figure 3. When working on the curve with a one per cent droop the entire resistance range is covered with only a 0.05 watt change in the driver coil. The change in power output of the Mercurystat may be say five kilowatts so that the power amplification, or ratio of output to input is 100,000. Lower values of amplification can be obtained by merely reducing the spring force. This will result in lower coil currents and a less perfect matching between the negative stiffness of the magnetic circuit and the positive stiffness of the spring. Different amounts of droop secured in this manner are shown by the curves in figure 3. The slight nonlinearity in response can be eliminated by grading the external resistance between steps to give a linear relation between input and output currents.

Changes in temperature and in atmospheric pressure may cause small variations in the calibration of the Mercurystat. The amount of these variations depends upon such factors as the type of drive, the dimensions of the Mercurystat, and its sensitivity when used in a regulating system. In any given application it is usually possible to proportion the design so that these variations are negligible. If the bellows position is positively fixed by the control, changes in atmospheric pressure will have no effect upon the calibration. Temperature changes will cause slight variations in the volume of the mercury which will change the height of the mercury column. These changes can be

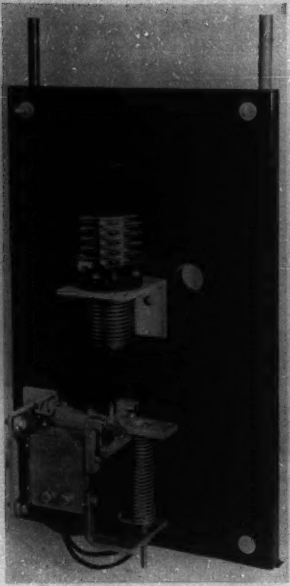

Figure 2. A 40-step Mercurystat and driver

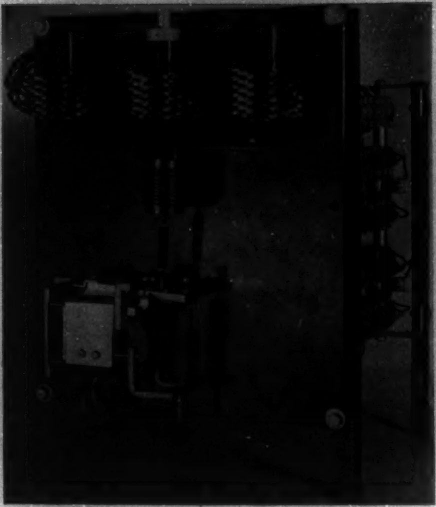
Figure 4. Three-phase Mercurystat



kept small by decreasing the volume of mercury with a plug as shown in figure 1.

If the Mercurystat is used in a regulating system where the bellows are operated by an electromagnetic driver as shown in figure 2, the amount of error caused by variations in temperature and atmospheric pressure will depend upon the droop of the regulator. For example, if the regulator has no droop, any change in the height of the mercury column as a result of changes in temperature and atmospheric pressure will be corrected for with no error. If the regulator has a one per cent droop and changes in temperature and atmospheric pressure should cause the Mercurystat to swing through say 20 per cent of its range, the regulator will correct for this swing with a resulting error equal to one-fifth of one per cent. Errors due to variations in atmospheric pressure can be eliminated by attaching a duplicate sealed bellows to the driving arm in such a position that any change in atmospheric pressure will give equal and opposite moments to the driver arm. By making the volume of this second bellows equal to the gas space at the top of the mercury column, variations resulting from pressure changes of the internal gas with temperature can also be eliminated.

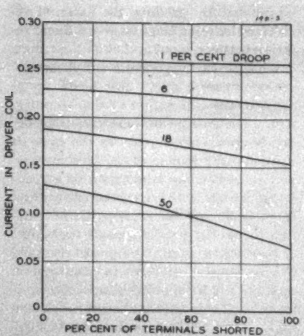


Figure 3. Mercurystat and driver response

Applications

Numerous applications for the Mercurystat will be apparent to those who have worked with regulators and power amplifiers. A few applications will be briefly described to show how it can be adapted to typical control problems.

A Mercurystat designed for controlling the speed of three-phase, wound rotor motors is shown in figure 4. Three sets of terminal assemblies are mounted on a bar which has internal holes connecting the three mercury columns to a common bellows. Movement of the bellows will then give equal changes in external resistors which are connected in each phase of the rotor. If a voltage proportional to speed is applied to the electromagnetic driver of the Mercurystat, it will serve as a stimulus for regulating any speed within the range of the control resistance. When load changes occur which cause the motor speed and the voltage on the Mercurystat driver to change, the Mercurystat will automatically adjust the external resistors to maintain a constant motor speed. The control voltage, proportional to speed, can be obtained from a small electric tachometer driven by the motor. In place of an electric tachometer the voltage across slip rings can be rectified and used to control the Mercurystat. When the motor slip increases, this voltage will increase and the Mercurystat will short out resistance to bring the motor back to its regulated speed.

In another application of speed control, a special speed cycle was made possible by using a cam to drive two Mercurystats. One Mercurystat is used to change the resistance in the rotor of an a-c motor to adjust speed. The other Mercurystat is used to secure rapid changes in speed by controlling the dynamic braking of a d-c generator mounted on the same shaft as the a-c motor. This latter control is obtained by changing the resistance in series with the armature and series field of the d-c generator. The bellows of the two Mercurystats are so coupled that when

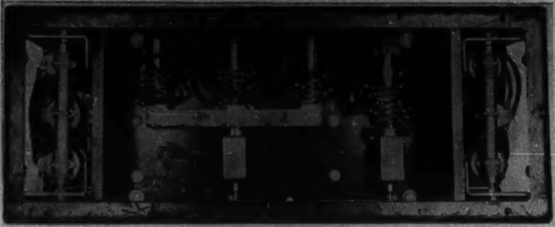

Figure 5. Special speed controller

one is inserting resistance in the rotor of the a-c motor to reduce speed, the other is shorting out resistance in the d-c generator to give increased dynamic braking. This arrangement gives a large number of speed settings which can be reached very quickly by adjusting the main control cam. Figure 5 shows this form of speed controller as built to meet special space limitations. The resistors required by the control are mounted on the sides and in the back of the Mercurystat panel.

In some applications where the operating stimulus is at a high power level, the amplification of the Mercurystat is not important. This was the case in applying the Mercurystat to a speed matching regulator. Here the Mercurystat was used because of its high-current capacity and its sealed-in contact structure. The Mercurystat is shown in figure 6 mounted on a panel which is supported by the synchronous motor and differential housing of an experimental speed matcher. It is a 100-step unit with the terminals connected to control resistors mounted in the rear of the panel. The synchronous motor drives one-half of the differential, and the cone pulley, located just below the Mercurystat resistors, is connected to the other half through the hollow shaft of the synchronous motor. If the speed of the cone pulley differs from the reference speed of the synchronous motor the movement of a traveling nut in the differential is transmitted to a lever on the side of the housing which operates the bellows of the Mercurystat in a direction to change the field excitation of the regulated motor and correct for the error in speed.

It will be apparent to those familiar with the design and application of voltage regulators that the new device can also be applied in this field. If used with an exciter, the Mercurystat has sufficient power capacity to regulate the voltage of medium and large size a-c generators. The circuits used in such regulating systems along with problems of stability and damping, have been described in a previous paper.[2]

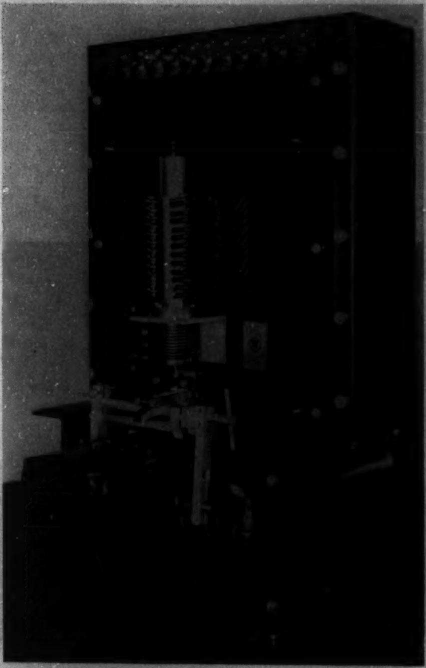

Figure 6. Speed-matcher regulator

Summary

The principal design features, along with several typical applications, were described for a new form of mercury rheostatic element which has been designated as the "Mercurystat". The unique features of the Mercurystat are its large number of hermetically sealed mercury contacts and the small force and travel required for their operation. It was shown that relatively large amounts of power can be controlled by the Mercurystat and because of the small input power required for its operation, power amplification in the order of 100,000 can be obtained. The performance of this new device along with its simplicity and absence of wearing moving parts should find many applications for it in automatic control systems.

Modern Motors Serve City Transit Systems

W. J. CLARDY
MEMBER AIEE

C. A. ATWELL
ASSOCIATE AIEE

Synopsis: City transit motors operated today include many new mechanical and electrical features. Modern vehicles differ greatly from those of a decade ago and propulsion motors contributed substantially to the advances achieved. Meeting present-day needs has required designs for 300 and 600 volts involving extensive use of new materials, application to new types of drive, and suitability for dynamic braking. Mechanical design includes unusual developments in frame construction, method of mounting, lead arrangement, ventilation, housings, and bearings. Compactness has led to ingenuity in brushholder arrangement to secure accessibility. Armatures require judicious selection of materials for shafts, cores, and commutators as well as special seasoning and balancing procedure. Electrical design betterments have been introduced in armature slots, armature coils, field coils, and insulation. Provision for quietness and good commutation are also salient points. The new designs have resulted in high electrical and weight efficiency for series motors used on Diesel-electric busses, trolley coaches, and street cars in comparison with old type machines. Excellent commutation has produced outstanding stability at rapid accelerating and dynamic braking rates. Vehicle performance is exceptional with respect to safety, operating efficiency, available selection of accelerating and braking rates, and the broad speed range of the dynamic brake.

"PEOPLE must be served" has become the success axiom of city transit operators. Creative action has resulted to keep pace with present-day travel demands. The development of modern vehicles is closely associated with progress in propulsion motor construction. Machines in use today include many new mechanical and electrical features. Weight below ten pounds per horsepower, compared with almost three times this figure for old machines, is a measure of what has been achieved with modern designs. These advances have made possible the Diesel-electric bus, trolley coach, and the modern street car.

Performance Requirements

Motors used today differ greatly from older types and are the result of the solution of a number of interesting problems. Machines have been designed for 300 volts and applied two in series to reduce weight in comparison with 600-volt motors. In order to meet the limitations imposed by the space available, new materials have been used extensively. This has assisted in meeting the demand for motors much smaller than older types producing the same horsepower.

The change to different types of drive with spring-supported motors required fundamental departures from previous practices. Gear cases and axle bearings were no longer needed. The new method of mounting protected motors from road shocks and thus permitted lighter construction. An increase in gear ratio was practicable which gave a "step-up" in armature speed and a decrease in over-all weight. Modern vehicles use the motors for stopping as well as starting which introduced the added duty of dynamic braking.

Mechanical Design Features

An evolution has occurred in mechanical design features because of the experience gained during the transition from the axle-hung to spring-supported type machine. The rolled steel frame has replaced the cast type. This new construction has important manufacturing advantages and provides a more effective magnetic circuit. Hidden casting blowholes are eliminated, a condition which often reduced the area of the magnetic section and caused variation in speed between individual motors built in accord with identical designs. There is ample room for original assembly or servicing of the poles field coils, and field wiring between coils The method of motor support is dependent on the vehicles. For example, trolley coach motors are held at the two ends by feet cast on the housings which are suitable for bolting to horizontal cross members. Modern street car motors are supported by clamping them in circular grooves cut in the outside of the frames.

Flexible stranded cable with rubber insulation and heavy rubber jacketing is used for leads. Protection is provided for passage through frames by heavy rubber bushings. Four leads are needed by a series motor, two for the armature with the interpole field, and two for the main field. When field shunting is applied to increase speed, it is obtained by applying a shunt across the main field. The older method of field tapping required an additional lead. A novel terminal construction is used on the modern street car motor which employs four insulated stud type terminals. The construction is illustrated in figure 1. The terminals are made of brass and are tapered at the outer end. A stud bolt between each pair is used for clamping the internally tapered terminals of the car wiring tightly against the motor terminals. This scheme permits easy removal of the car wiring from motors in the restricted mounting space available on trucks.

Commutator and fan end housings are removable castings that fit accurately into the bore of the frame and are bolted to its extremities. Each housing includes its bearing assembly. The commutator end housing supports and provides access to the brush holders as well as being an inlet for the ventilating air. The fan end housing has space for the

Paper 41-104, recommended by the AIEE committee on land transportation, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 17, 1941; made available for preprinting April 30, 1941.

W. J. CLARDY and C. A. ATWELL are both transportation engineers of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

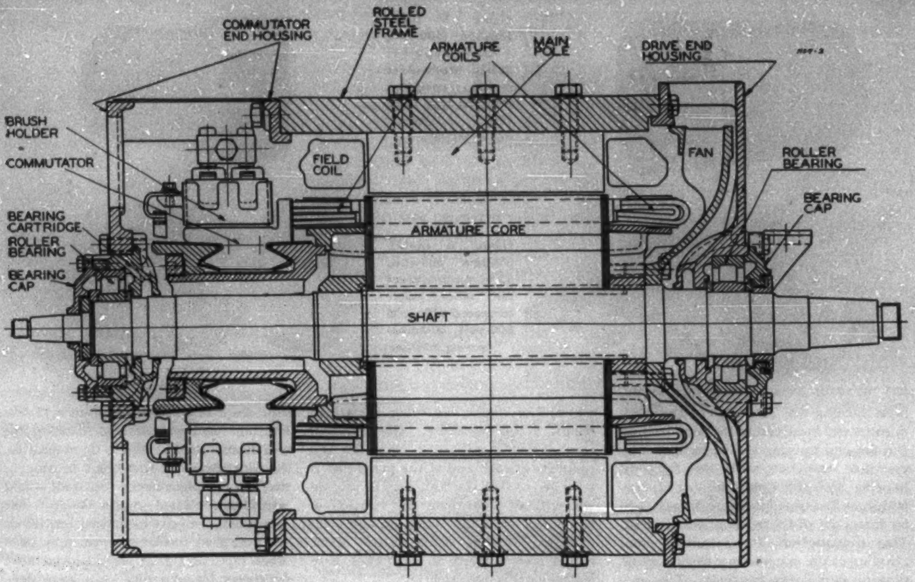

Figure 2. Construction of 600-volt, 140-horsepower trolley coach series motor

fan and is built with air outlets proportioned to give quiet and efficient discharge of the air leaving the fan blades. Adequate ventilation is obtained by the armature shaft fan. It draws air in at the commutator end, through spaces between the field coils and over the surface of the armature, as one path, and through longitudinal ducts in the armature core as a parallel path.

The support of bearings in housings and the method of enclosure have been carefully analyzed in conjunction with recent development work. Roller or ball bearings with grease lubrication are standard. Performance records are exceptional for the designs of the past five or six years in comparison with those of 10 or 12 years ago. This is especially true in the case of roller bearings. It can be attributed to the proper initial internal clearances, the method of mounting and assembly in the housings, and the effective enclosure of the grease space by metal labyrinth seals.

The housing and bearing construction shown on figure 2 is typical. At the fan end, the bearing fits in a bore in the housing and has an outer bolted cap. At the commutator end, the bearing is carried in a separate cartridge having an outer enclosing cap. This cartridge fits in a bore in the commutator end housing and is also bolted to it. The commutator end roller bearing is of the thrust type and locates the armature longitudinally. A "free" type roller bearing is used at the fan end, allowing for expansion and contraction in the length of the shaft with respect to the stationary parts. An important advantage of this type of construction is that the complete armature with bearings may be removed without exposing either of the bearings to dirt. Such a removal is made by taking out the

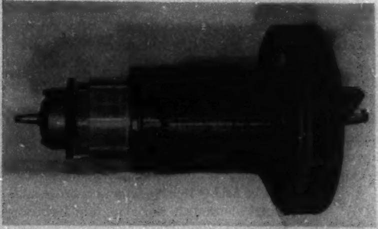

Figure 3. Armature for 600-volt, 140-horsepower trolley coach series motor

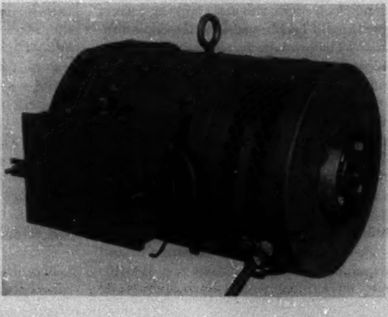

Figure 4 (right). Diesel-electric bus motor for use with 125-horsepower power plant

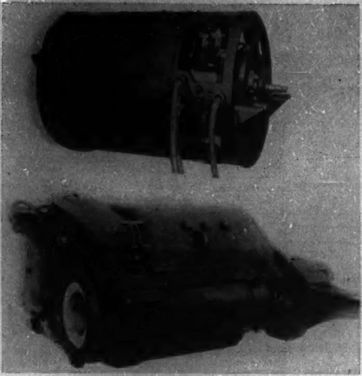

Figure 5 (left). Modern 600-volt, 140-horsepower trolley coach series motor compared with old type 600-volt, 125-horsepower machine

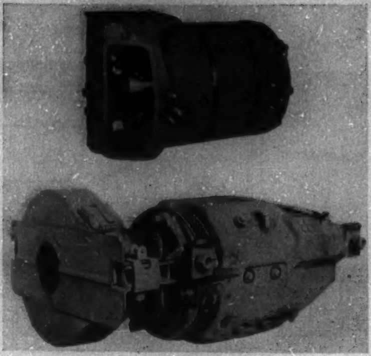

Figure 6 (right). Modern 300-volt, 55-horsepower street car series motor compared with old 600-volt, 50-horsepower machine

bolts holding the cartridge to the commutator end housing and the bolts holding the fan end housing to the frame. The complete armature with the fan end housing and the commutator end cartridge, as illustrated in figure 3, may then be drawn out of the motor at the fan end. This construction also permits a final grinding of the commutator surface while running in its own bearings. The procedure is to support the armature and housing assembly in a grinding fixture and rotate the armature by a small driving motor coupled to the shaft while grinding the commutator surface.

The commutator end housing construction is closely connected with the support and accessibility of the brush holders. Carbon brushes are subject to wear and the brush holders must be available for easy inspection and replacement of carbons. The brush holder used is the bronze box type with two insulated supporting pins. This provides a simple and accurately located mounting with means for radial adjustment as the commutator surface wears to a smaller diameter. Brush holders have adjustable steel clock springs to maintain the correct pressure of brushes against the commutator. The pressure finger and the carbons have flexible copper shunts. Spacing and position are set during manufacture by means of a jig which accurately locates the center line of the brushes relative to the center line of the commutating pole faces. After this setting is made, bolts holding the brush holder support block to the housing are welded in place. Individual brush holders are interchangeable.

Armatures are solidly constructed and capable of operating at high speeds without mechanical distortion. High-grade material in shafts and other parts contribute to this durability. The laminated core assembly with cast armature coil supports at each end of the punchings is arranged so that the shaft may be pressed out without disturbing the relation of punchings, armature windings, and commutator. Broken shafts rarely occur, but in case of injury to shaft ends, easy replacement is essential.

Commutators are seasoned at high temperature while being rotated near the maximum operating speed. This allows the mica between bars to become set to withstand movement at the maximum temperature and speed encountered in service. The seasoning process is a series of heatings and tightenings carried on under these conditions until the commutator runs smoothly either cold or hot at maximum speed. Armature balancing in a modern dynamic balancing machine is essential. The best construction provides for two dynamic balancings: one before the armature is wound, and one afterward. All of the unbalance of the armature except that due to the winding is permanently eliminated and if the armature is rewound, only the unbalance of the armature winding need be provided for. The coil support castings at each end of the punching assembly are provided with balancing pockets into which the required amount of melted lead is poured. This takes care of the unbalance before winding. The small unbalance of the armature winding is compensated for by adding solder to the wire banding on the armature coil ends.

Electrical Design Features

The electrical design of a d-c motor involves the selection of the number, size, and shape of the armature coils and slots and the arrangement and shape of the conductors in the slot. Commutation, flashing characteristics, and heating as well as complete motor size and weight are closely related to slot design. The newly developed insulating materials such as glass insulated conductors, glass fiber tape, and glass cloth backed mica wrappers for armature coils have done much to increase the efficiency of the slot design. The ratio of cross section of copper in the slot to the total cross section of the slot itself has been raised without sacrificing factors affecting commutation, flashing, and heating. Slot wedges for retaining the armature coils in the slots have replaced the use of wire bands on the core. The material used for wedges is usually micarta. The wedge construction is more reliable mechanically than core bands at high peripheral speeds. Their use eliminates eddy current losses produced in bands and the detrimental effect of core bands on commutation.

The small size of modern motors and the use of form wound, single turn, wave type armature coils, makes armature winding a simple procedure. Individual armature coils are varnish treated before winding and the wound armature is given a series of heatings, dippings, and oven bakings using a newly developed insulating varnish. The new varnish has improved characteristics of dielectric strength, more permanent set after baking, and provides a smoother surface that is more repellent to dirt and oil.

The field coil arrangement is made symmetrical around the armature by using the same number of commutating coils and poles as main coils and poles, usually four of each. The coils are either formed of strap copper wound on edge or flat

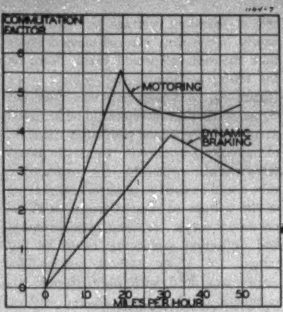

Figure 7. Commutation curve for 600-volt, 140-horsepower trolley coach motor

wound in sections depending on the particular design involved. The field coil construction has also benefited from the available new insulating materials. They occupy a minimum of space and are formed to fit accurately between the pole tips and the frame. The complete frame, pole, and coil assembly are given a dipping and baking treatment with insulating varnish similar to that used for armatures. A smooth hard coating over the insulated surfaces of coils and cable or strap lead connections is obtained. It has high dielectric quality and is resistant to water, dirt, or oil. Modern motors use insulation designated by the AIEE rules as class *B*. The materials consist principally of asbestos, mica, and glass fiber and are little affected by high overload temperatures often encountered in transit service.

Quiet operation is essential for use on vehicles with rubber tires or resilient wheels. Possible sources of motor noise are the brushes, bearings, fan, or armature teeth. All of these noises have been reduced in modern designs. Brush chatter or squeak is prevented by brush holder construction and smooth riding brushes. Bearing noise has been lowered to the point that a noisy bearing indicates that it is defective and must be replaced. Windage noise has been minimized by streamlining fan blades and air outlets. Magnetic noise from the armature is avoided either by skewing the slots or by using slots parallel to the shaft and giving careful attention to shaping of main pole tips and air gap taper. The latter method is more desirable because of greater ease of winding coils in straight slots and because slot skewing often widens the commutating zone under the commutating pole to an undesirable degree.

Commutation and flashing characteristics have been the subject of considerable study to secure long brush and commutator life and to permit the use of service dynamic braking. The higher rotational armature speeds tend to make this problem more difficult. This is largely offset by the use of single turn armature coils which compare with two or even three turn coils for older type machines. Also, the use of two 300-volt motors in series to utilize 600 volts from the trolley, has permitted designs with better commutation and flashing factors. In the case of the single motor for trolley coaches, a 600-volt commutator is required. However, the motor is of sufficient size to permit the use of a single turn armature coil, and other parts affecting commutation and flashing can also be well proportioned. While the commutation and flashing characteristics of a d-c motor are closely related, the design factors favorable to one are somewhat opposed to the other. A satisfactory balance must be obtained that will meet the requirements for both. For example, fewer armature conductors favor low "sparking volts" under the brush, but freedom from flashing calls for sufficient commutator bars, with the required armature conductors, to prevent the maximum volts per bar from becoming excessive at the maximum armature volts encountered in service. A flashover is started by the voltage between adjacent commutator bars becoming so high that arcs between bars are maintained after these bars pass under the brush. One precaution is to avoid main field strength distortion incident to the effect of the armature, thus preventing a peak in the field form. The series motor inherently averts an excessive armature distorting effect because the ratio of armature to field ampere turns is constant and relatively strong in dynamic braking. Under the condition of acceleration with shunted field, some distortion can be allowed in the field form as the terminal voltage is never above the trolley voltage. The field shunt is made with the proper amount of inductance so that sudden changes of load will cause no transient weakening of the field. Good commutation under the condition of maximum accelerating amperes requires that the magnetic circuit of the commutating poles be unsaturated.

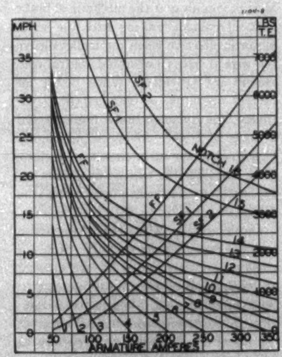

Figure 8. Acceleration curves for 600-volt, 140-horsepower trolley coach motor

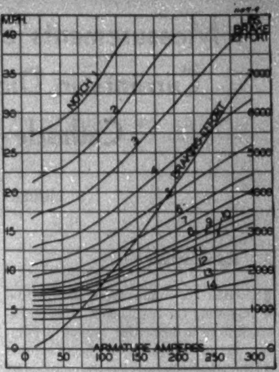

Figure 9. Dynamic braking curves for 600-volt, 140-horsepower trolley coach motor

Typical Modern City Transit Motors

The Diesel-electric bus motor, designated as the 1435 type, is illustrated in figure 4. The machine is capable of handling the output of a 125-horsepower engine-generator power plant. The weight of the motor is 880 pounds which is exceptionally light for the available performance capacity.

The modern trolley coach would be impractical without the 1442-type motor which has been designed for this vehicle. The machine is illustrated in figure 5. It rates 140 horsepower at 600 volts and weighs 1,360 pounds—less than 10 pounds per horsepower. A picture of an old type 125-horsepower motor is shown in the same illustration to give a relative comparison. The latter unit weighs 3,430 pounds excluding gear and gear case—over 27 pounds per horsepower.

The development of the present-day street car is closely associated with the 1432-type, 300-volt motor shown in figure 6. This is a 55-horsepower machine

Measurements of Pre-Breakdown Currents in Dielectrics With a Cathode-Ray Tube

HUBERT H. RACE
FELLOW AIEE

A. Introduction

In order to obtain more information regarding the mechanism of electrical breakdown in insulating liquids, a number of experimenters[1,2,3] have studied current flow as a function of applied voltage, using high-sensitivity d-c amplifiers with indicating instruments having relatively long-time constants. Such instruments will not follow rapid changes in current where the time intervals are of the order of milliseconds or less. Therefore we decided to investigate the possibility of using a cathode-ray tube as a current detector to follow current changes just preceding breakdown. This paper describes current measurements in liquids with 200-microsecond impulse voltage waves and current measurements in liquids and solids with gradually increasing unidirectional voltage applied to the specimens.

B. Measurements on Liquids Using Balanced Impulse Circuits

Breakdown in liquids gives no warning preceding its occurrence which can be used to trigger the sweep of a cathode-ray tube so as to make a breakdown self-indicating. Therefore we applied to the test cell a transient voltage increasing at nearly a constant rate of such a value that the test cell would break down on the rising portion of the voltage wave (figure 1). A sweep trip was built designed so that the sweep could be initiated at any predetermined time after the start of the voltage transient. Since the sweep time was also adjustable, the cathode-ray tube could be used to observe any portion of the voltage or current transient if the necessary single transient writing speed and deflection sensitivity could be obtained. A 15-kv cathode-ray oscilloscope[4] was used with photographic attachment to obtain the desired writing speed.

Because of the high rate of voltage rise necessary to obtain breakdown in one sweep of the cathode beam, the cell capacitance charging current would be much greater than the conductance current. Therefore two balanced, opposing impulse circuits were used, as shown in

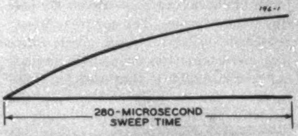

Figure 1. Impulse voltage-time curve

Paper 41-96, recommended by the AIEE committee on basic sciences, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted January 29, 1941; made available for preprinting April 11, 1941.

Hubert H. Race is research engineer with General Electric Company, Schenectady, N. Y.

The author is indebted to R. A. Pfuntner for assistance in making these measurements and to N. Rohats for suggestions and circuit details connected with the cathode-ray equipment.

---

weighing 695 pounds—just over 12 pounds per horsepower. The same picture includes an old type 50-horsepower 600-volt motor and gives a visual indication of the progress made in the new design. The earlier type weighs 2,000 pounds or 40 pounds per horsepower.

Performance Characteristics

Satisfactory commutation requires minimum sparking at the brush faces under the most unfavorable combination of load and speed encountered in service. In figure 7, the "commutation factor" is a measure of the average voltage between bars under the brush. This figure shows how this factor varies throughout the speed range for motoring and dynamic braking for a 600-volt series trolley coach motor. The motor design is such that the maximum value of this "commutation factor" is below that which produces sparking at the brush faces. It is lower for dynamic braking than for motoring.

The series motor has the inherent advantage of a rapidly increasing dynamic braking effort as speed is stepped up. Thus, when a vehicle is gaining speed down grade and the dynamic brake is applied, any desired balanced condition may be quickly obtained. There is no possibility of the motor reaching an unstable condition and permitting the vehicle to run away if the mechanical brake fails. Dynamic braking with the series motor is effective when the trolleys leave the wire if battery operated control contactors are provided. When power for control operation is obtained from the trolley, the dynamic brake is unaffected as long as trolley voltage is sufficiently high to close the main circuit contactors. Thus, considerable voltage drop may occur without adversely influencing the dynamic brake.

Accelerating performance of the series motor is exceptionally smooth. Rates of acceleration, determined by the amount of pedal advance, permit an operator to start a vehicle at a rate selected to conform to traffic requirements. This gives the operating flexibility so necessary in city service. A set of acceleration curves, applicable to the modern trolley coach, is shown in figure 8.

The range of the dynamic brake obtained with the series motor is unusually broad. This is illustrated by the braking curves shown in figure 9. Braking current is effectively regulated to maintain any selected rate of braking up to the maximum capacity of the motor equipment. The uniform motor current which is obtained provides equal tractive effort values on all notches and thus maintains the desired braking rate. The series motor is capable of developing its full braking rate down to three or four miles per hour if these low speeds are desired.

New Motors Extensively Used

The new designs of motors for Diesel-electric busses, trolley coaches, and street cars have been generally applied on city transit systems. The machines available are the product of considerable engineering effort to reduce weight, increase efficiency, and improve output. Results are creditable as a contribution which has assisted in the development of modern transit vehicles.

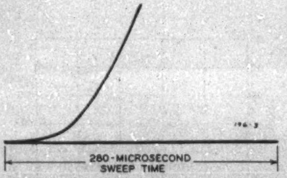

Figure 3. Breakdown current in a high-conductivity liquid

Diphenyl oxide + diphenyl

figure 2.[9] An adjustable air capacitor was used to balance out the capacitance current of the test cell. Under these conditions the voltage between point (*A*) and ground should be zero if the conductance current in the test cell were zero. Also if the cell conductance current were appreciable the voltage drop across the one-megohm resistor could be indicated by the cathode-ray deflection as a measure of this current.

Proper operation of this circuit depends upon equal voltage-time transients of opposite polarity being applied to the two sides of the circuit. The charging currents are then equal and opposite so that only the voltage drop due to the conductance current appears across the measuring resistor. If this resistor was larger than one megohm, the capacitance of the leads and cathode-ray oscillograph deflection plates provided a comparatively low-impedance shunt for the fast transients. Even with one megohm it became necessary to correct the resulting curves, both for the deflection plate capacitance and the circuit unbalance due to the drop in the resistor.

Good results were obtained on a mixture of commercial diphenyl and diphenyl oxide which was continuously circulated through a filtering and degasifying system.[5] Figure 3 is a good example of the type of curve obtained, and figure 4 shows the corrected curve plotted with time, current, voltage, and resistance scales. The pre-breakdown currents in this liquid were very high (one or two milliamperes). However, lower conductivity liquids could not be studied because of insufficient sensitivity. Figure 5 shows a typical shot taken on a low viscosity cable oil (GE number 5314) with a 22-microsecond sweep. After breakdown, the high-frequency damped oscillation is determined by the circuit constants, not the liquid. No pre-breakdown current can be seen, meaning *that the current was less than 10^{-4} amperes up to within a fraction of a microsecond of breakdown.*

C. Measurements on Liquids Using Gradually Increasing Voltage and Photographing Repeating Sweeps on a Cathode-Ray Tube

1. Apparatus

At a low rate of voltage application the capacitance charging current is negligible. Methods were worked out to trip the sweep circuit repeatedly at two-millisecond intervals and to use a continuous feed movie camera without shutter to record the resulting single traces. A 15-kv tungstate screen tube was used to get high photographic intensity. The film moved approximately parallel to the sweep direction at such a speed that successive sweeps uncovered or progressed about one-fifth of the length of a single trace on the film. A resulting hypothetical pre-breakdown current is shown schematically in figure 6. The slowly increasing unidirectional voltage-time curve was measured with a photoelectric recorder.[5] A manually operated selector switch (figure 7) was used so that the operator, while watching the cathode tube deflection, could vary the sensitivity and thus follow a slowly rising current as the voltage was gradually increased. The photographic setup was arranged so that the operator could view the tube screen from the side during the entire run. The 10^5 and 10^6 ∽ resistors were wire wound, the others were electrolytic, using solutions of tetrabutyl ammonium picrate in a mixture of diphenyl and diphenyl oxide. Sealed off glass cells were used to prevent resistance changes with time and the concentration and cell dimensions were varied to give the desired resistances. Since the sweep time used is about 40 microseconds and the sweep interval is 2 milliseconds, we have a 2 per cent prob-

ability of catching a breakdown transient if it is only of the order of microseconds duration.

2. Current-Time Data for a Low-Viscosity Mineral Oil (GE 5314)

For these experiments open cells (figure 8) having spherical electrodes of three different metals were used. The electrodes were polished on a dry clean buffing wheel. Then the electrodes and cells were chemically cleaned, steamed, and dried in a 100-degree centigrade oven as described by Dornte.[6]

Table I shows the last current readings and the breakdown gradients for this series of tests and figures 9 and 10 show the current-time data taken at intervals from the movie film record of the cathode-ray tube deflections. *These data give additional evidence for the conclusion that the conditions of the experiment particularly regarding the electrode surface are the important factors governing pre-breakdown current as well as the breakdown gradient.*[3,5]

3. Pre-Breakdown Current in Heptane

A hemispherical electrode, closed cell prepared and filled with *pure, dry* heptane by Dornte[3] was measured first with his FP54 amplifier below breakdown and then up to breakdown with the equipment described in this paper. The data taken from the records of the latter measurements are shown in figure 11.

It is interesting to examine these data in terms of two possible explanations of their cause. The Wien-Onsager[7] derivation* would predict that if $\log_{10}(I/E)$ is plotted against $\sqrt{\text{volts per centimeter}}$, the asymptotic slope equals

$$\frac{0.434}{T}\sqrt{\frac{8\times 9.64}{\epsilon'}} \tag{1}$$

for this experiment with heptane $\epsilon'=1.91$, $T=300$ degrees Kelvin so that the limiting slope $=0.0092$. Figure 12 shows the data for heptane plotted in this form with the theoretical slope indicated.

Baker and Boltz[1] suggested that the limiting factor in conduction might be a potential barrier at the electrode-liquid interface so that a modified Schottky relation should apply.** Their derivation indicates that if $\log_{10} I$ is plotted against $\sqrt{\text{volts per centimeter}}$, the limiting slope should be given by the expression

$$1.91(\epsilon')^{1/2}/T \tag{2}$$

This relation gives a slope of 0.0089 for our data.

On the other hand, LePage and DuBridge[8] do not agree with the Baker-Boltz derivations and arrive at the relation.

$$1.91/(\epsilon')^{1/2}T \tag{3}$$

For heptane this gives a slope of 0.0045. The data for heptane are plotted in figure 13 with these two slopes indicated. The results for heptane fit the Onsager and Baker-Boltz derivations better than the LePage-DuBridge calculations.

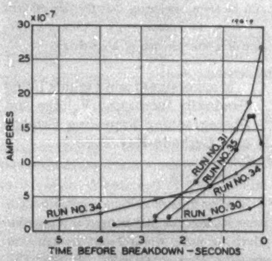

Figure 9. Pre-breakdown current in mineral oil

See table I

4. Pre-Breakdown Current in Conducting Liquids

To determine the effect of adding conducting ions, filtered, chemically pure toluene alone (run 66) and filtered toluene+0.025 per cent tetrabutyl ammonium picrate (run 72) were tested in the quartz cell with stainless steel spherical electrodes. The results are shown in figure 14. Before applying high voltage, the d-c resistance was measured at low voltage in each case as follows, run 66, $R=1.8\times10^{10}$ ohms, run 72, $R=8.8\times10^{8}$ ohms. The breaks in the current curves indicate definite changes in mechanism of conductance as the gradient is increased. Such breaks are commonly observed if the current-measuring equipment has a sufficiently wide range of sensitivity.

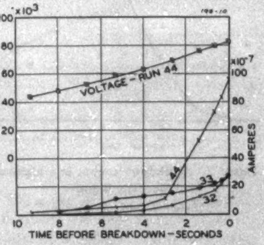

Figure 10. Pre-breakdown current in mineral oil

See table I

Since conducting ions have been added for run 72, the results should be checked against the Wien-Onsager theory. Therefore figure 15 is plotted but, contrary to expectations, the slopes of the conductances versus gradient lines were much

---

* This theory is based upon increased dissociation of ion pairs at increased field strengths.

** This theory assumes that the controlling factor in current flow is the ability of electrons to escape into the liquid from the electrode surfaces and therefore is limited by a "work function" similar to that involved in electron emission into gases.

Table I. Pre-breakdown Conditions in 5314 Oil

Run No.	Symbol	Shot	B.D. Gradient (Kv/Cm)	Current before B.D.× 10^{-10} Amperes	Resistance Before B.D.× 10^{-10} Ohms	Electrode Material	Electrode Spacing (Cm)

44	ϕ	1	550	96	0.86	Steel	0.15

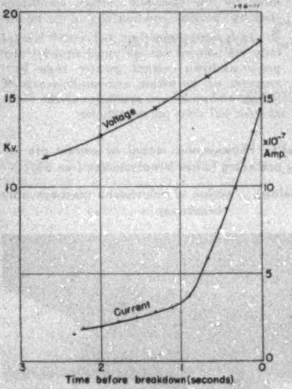

Figure 11. Pre-breakdown current and voltage in dry heptane

lower than would be required by the theory which predicts a slope of 0.008 for toluene. Likewise the same data are plotted in figure 16 to obtain a comparison with the potential barrier theory. The toluene containing conducting ions seems to check the LePage-DuBridge derivation but the toluene alone does not.

Unfortunately this investigation was discontinued before the above calculations were made so that the runs have not been repeated and checks are not possible at present. However, the results seemed worthy of reporting even though they are inconclusive as to the mechanism involved.

5. Discussion of Results on Liquids

In none of the breakdown records on liquids did we catch the breakdown transient. The last trace on each record was substantially like those immediately preceding it, showing the slowly increasing current with increased voltage as shown in figures 9, 10, 11, and 14. It seems reasonable to conclude that the observed current increases are ionic but that the final breakdown is electronic and occurs very fast (fractions of microseconds, see figure 5). Furthermore it seems that the pre-breakdown ionic current may be unrelated to the breakdown electronic current since the results of many investigations indicate that the breakdown gradient appears to be affected more by electrode surface conditions than by the ionic conductivity of the liquid.

D. Pre-Breakdown Currents in Solids

A number of experiments were tried to see whether the methods described in part *C* could be used to measure current just before breakdown in solids. The test pieces were prepared by drilling 3-millimeter coaxial holes from opposite ends of a 1.5×1.5×7-centimeter test piece. The ends of the holes were made hemispherical with a special reamer and the thickness of the test section between the ends of the holes was accurately measured with a micrometer. Very finely divided graphite was then introduced into each hole and brass rod electrodes with rounded ends driven lightly into the graphite. In this manner the field distribution which exists between spheres in a homogeneous dielectric was obtained and corona between the electrode and the dielectric was eliminated.

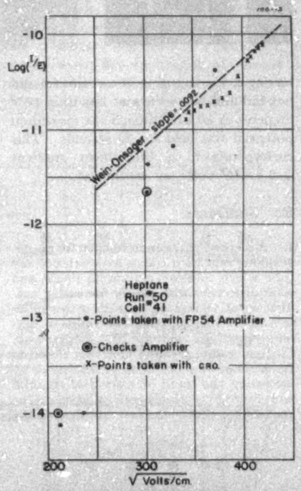

Figure 12. Plot of data for heptane to compare Wein-Onsager calculations

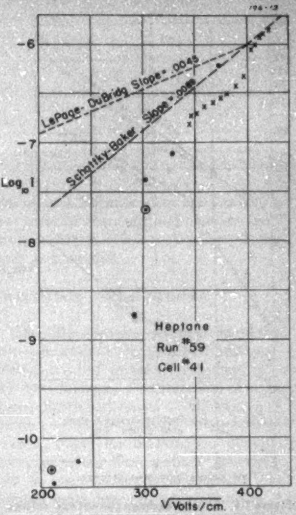

Figure 13. Plot of data for heptane to compare with Shottky-Baker hypothesis

Figure 18 shows a polystyrene specimen (run 53) after breakdown. This specimen had a test thickness of 0.053 centimeter and broke down at 77 kv, giving a breakdown gradient of 1.45×10^6 volts per centimeter. The current in this specimen was less than 1×10^{-8} amperes up to within four milliseconds of failure. The current record just before failure is interesting (figure 17), since the two sweeps before failure show currents of 40 and 106×10^{-8} amperes, respectively. Then failure occurred before the next sweep, which was back on the zero line. Another polystyrene specimen having a spacing of 0.033 centimeter did not fail at 83 kv, when tested at 100 degrees centigrade. This corresponds to a gradient >2.5×10^6 volts per centimeter (6,350 volts per mil). A third specimen at 100 degrees centigrade having a test spacing of 0.013 centimeter failed at 34.2 kv corresponding to a gradient of 2.6×10^6 volts per centimeter (6,600 volts per

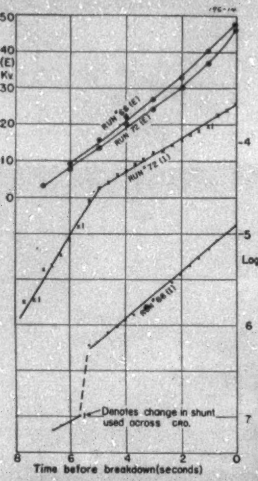

Figure 14. Pre-breakdown current and voltage data for chemically pure toluene (run 66) and toluene + tetrabutylammonium picrate (run 72)

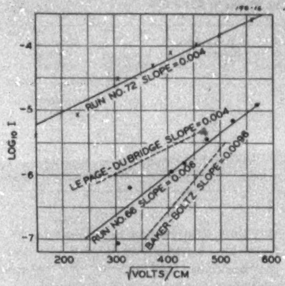

Figure 16. Plot of data for toluene alone (run 66) and toluene + 0.025 per cent tetrabutylammonium picrate (run 72)

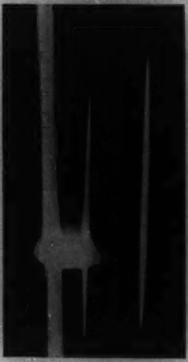

Figure 17 (left). Photographic record of current rise immediately preceding failure in polystyrene (run 53)

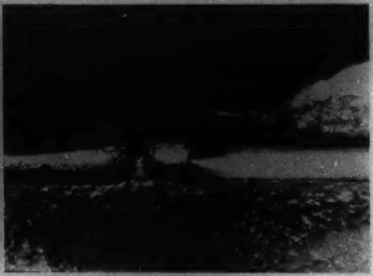
Figure 18 (below). Section of polystyrene specimen after breakdown



mil). None of these specimens showed any measurable current before breakdown.

Several specimens of polyvinyl formal resin were tested in the same way. No pre-breakdown current was observed, the failure having occurred between successive sweeps in each case. One specimen having a spacing of 0.038 centimeter did not fail and had a current less than 10^{-8} amperes at 86 kv although the maximum potential was held for 30 seconds. This corresponds to a breakdown gradient $>2.3\times10^6$ volts per centimeter.

E. Summary

1. A method has been developed for photographing repeating traces on a cathode-ray tube which measure current in liquid and solid dielectrics with slowly increasing unidirectional voltage up to within two milliseconds of breakdown. The range of current sensitivity is from 10^{-8} amperes up. Current values at time intervals closer to the breakdown point could be measured by increasing the speed of motion of the film and decreasing the sweep interval. The probability of catching fast transient of the order of one microsecond duration is only 2 per cent (ratio of sweep time to sweep interval).

2. In liquids, the evidence so far obtained leads to the tentative conclusion that the final breakdown current increases from a substantially steady value to failure in fractions of a microsecond. This indicates that the final breakdown mechanism is electronic.

3. In liquids, it appears also that the pre-breakdown ionic current may be unrelated to the breakdown electronic current since the breakdown gradient appears to be affected more by the electrode surface conditions than by the ionic conductivity of the liquid.

4. In polystyrene and polyvinyl formal only one record was obtained showing any pre-breakdown current greater than 10^{-8} amperes up to within two milliseconds of failure at breakdown gradients of the order of 2.5×10^6 volts per centimeter.

Bus Protection Independent of Current-Transformer Characteristics

G. STEEB
MEMBER AIEE

Synopsis: The paper describes the installation and operating results of a bus protective scheme, which uses a combination of high-speed directional ground relays on all sources of fault current and high-speed plunger type blocking relays on all outgoing circuits. The scheme described is independent of the ratios and characteristics of the current transformers.

Introduction

THE protection of station busses in the past has usually been accomplished by some form of differential relaying or by fault bus relaying.[1]

Differential relaying requires that the current transformers in each circuit on the bus have the same ratio and characteristic.[2] Sometimes auxiliary transformers are used to compensate for differences in the ratios of various current transformers.[3] It has often been necessary to give the differential relays a relatively high pickup and some time delay in order to prevent incorrect operations. The application of the harmonic current restraint relay has overcome some of the difficulties of differential relaying for bus protection.[4]

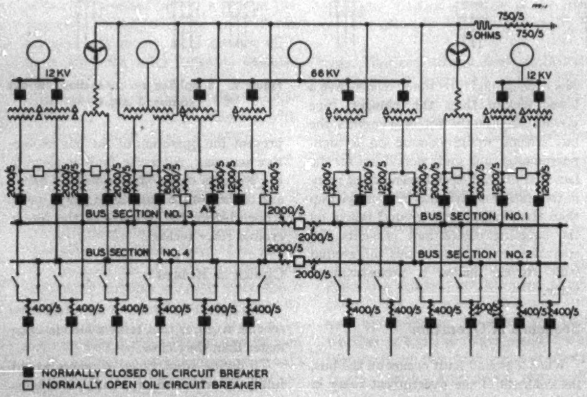

Figure 1. Circuit arrangement of 25-cycle, 22-kv outdoor station

Fault bus relaying requires that all equipment be insulated from ground and connected to a common fault bus, which is grounded through a current transformer which operates some type of relay.[5]

Neither of the above schemes could be applied in a practical way to the bus layout shown in figure 1. Since each feeder has only one breaker, and each pair of feeders has selector disconnects to the busses, the application of current transformers for differential relay protection would not be feasible. This station is a 22-kv outdoor station which was built 20 years ago and does not lend itself readily to the application of the fault bus method.

Description of Bus Scheme

The difficulties in applying either of the two conventional methods of bus protection resulted in the development of a scheme which uses a combination of high-speed directional relays on all sources of fault current and high-speed plunger type current relays for blocking on all outgoing circuits. The method developed can be used for protection against any type of fault, but, after consideration of the speed of operation of the protective scheme and of the fact that the majority of faults in an outdoor station start as one wire to ground or two wires to ground faults, it was decided to install only ground fault protection. The total relay time of the protective scheme is from one to two cycles* and it was felt that this time was sufficiently short to insure relay operation before ground faults have sufficient time to develop into three-phase faults.

Figure 2 shows the simplified a-c connections for bus sections 1 and 2. Figure 3 shows the schematic d-c relay connections for bus sections 1 and 2. The connections for bus sections 3 and 4 are similar to those shown for bus sections 1 and 2.

Each of the high-speed ground directional relays used on circuits which are sources of ground current has one coil connected in the station neutral ground and its other coil in the respective residual current circuit. When de-energized, the contacts of these relays are open, and they close when ground current flows toward the protected bus section. A specially designed *b* switch on the oil circuit breaker in each circuit is connected across the

Paper 41-99, recommended by the AIEE committee on protective devices, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 1, 1941; made available for preprinting May 5, 1941.

G. Steeb is with the Buffalo, Niagara and Eastern Power Corporation, Buffalo, N. Y.

[1] For all numbered references, see list at end of paper.

* All times given are on a 25-cycle basis.

normally open contacts of these relays to prevent the relay scheme from being inoperative when a circuit is out of service.

All circuits which are not sources of ground current are provided with high-speed plunger type ground relays, each having two contacts both of which are closed when the relay is de-energized. Since the outgoing circuits can be connected to either one of two busses, it was necessary to use one contact of each of these relays in the protective scheme of each of these bus sections. Thus the operation of these relays, when a fault occurs on a circuit off the bus, blocks the bus scheme of both bus sections to which the circuit can be connected. The contacts of these relays are continuously supervised by indicating lights.

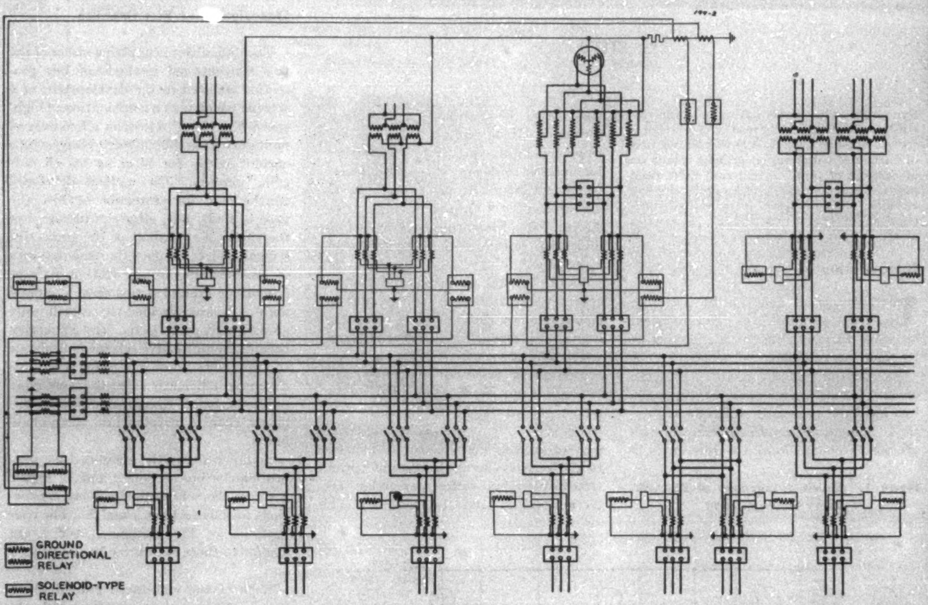

Figure 2. Simplified a-c connections for bus sections 1 and 2

The tie breakers to adjoining bus sections are equipped with both high-speed ground directional relays and high-speed plunger type ground relays with their contacts connected in parallel. Since an adjoining bus section may or may not be a source of ground current, it was necessary to install both types of relays. The normally closed contacts of the plunger type ground relays of the tie breakers also serve as *b* switches when the breakers are open. The tie breakers are normally open at least 90 per cent of the time.

To prevent an accidental operation of the bus scheme and also to prevent its operation on a high-resistance fault on a circuit off the bus, a high-speed plunger type overcurrent relay for each bus section is used in the station neutral ground. The contacts of this relay are connected in series with the operating coil of the gang trip relay, the normally open contacts of the ground directional relays, and the normally closed contacts of the plunger type ground relays for any bus section. Since the ground directional relays have a lower pickup than the plunger type ground relays on the outgoing circuits, the bus scheme would operate on a high-resistance ground fault were it not for the fact that the high-speed overcurrent relay in the station neutral has a higher pickup than the plunger type ground relays on the outgoing cables and prevents the operation of the bus relays on ground fault current below a predetermined value.

Sequence of Operation

When a ground fault occurs on the bus, the contacts of the overcurrent relay in the station neutral and of the ground directional relays in the circuits which are ground sources close, energizing the gang trip relay which trips all the power sources on the bus. Since the outgoing feeder circuits carry no fault current, the contacts of the relays on these circuits remain in the normally closed position.

When a ground fault occurs on a circuit off the bus, the contacts of the plunger type ground relay on the faulted circuit open before the contacts of the overcurrent relay in the station neutral and the ground directional relays close and thus prevent the operation of the bus protective scheme. After the fault is cleared, the contacts of the station neutral relay, and of the ground directional relays, must reopen before the contacts of the feeder ground relay reclose.

Choice of Relays

The correct operation of this protective scheme requires that relay contacts open faster than they close.

To decide what types of relays would fulfill this requirement, a number of tests were made in the laboratory, using an oscillograph, to check the relative opening and closing times of the various relays. It was found that satisfactory tolerance can be obtained between the opening of one contact and the closing of another, even on high-speed plunger type relays which are energized or de-energized simultaneously. The tests also showed that the contacts of five directional relays in series, operating simultaneously, give reliable results especially if the contacts are of the nonbounce type.

The relays that have been selected are all of simple design, and their operating times as recorded by the oscillograph, are described below.

The high-speed plunger type relays in the ungrounded circuits will open their contacts in a quarter of a cycle at all values of current greater than about 30 per cent above their setting, and after the current has been removed, the contacts will reset in one cycle. Of course the setting of these relays should be made as low as possible, because this determines the setting of the relays in the station neutral.

The high-speed plunger type overcurrent relays in the station neutral will close their contacts in a third of a cycle at the maximum obtainable current, which is 300 per cent of their setting. The closing time of the relay contacts increases, as the current decreases, i.e., at about 30 per cent above the setting the time will be one cycle and two cycles at 5 per cent above its setting. The contacts open in a quarter of a cycle after the relay becomes de-energized.

The high-speed ground directional relays have been adjusted to close their contacts in a time, varying from about two cycles at ten per cent above their setting to three-quarters of a cycle at the maximum obtainable current. These contacts will reopen in a quarter of a cycle after the relay becomes de-energized.

Additional tests showed that equally satisfactory results can be obtained with relays used on 60 cycles frequency.

Limitations of the Bus Scheme

1. If the unusual operating condition, should arise of a bus section being fed only through a tie breaker, it would be necessary to make the protective scheme nonautomatic on that section; since the *b* switches on every breaker that normally feed the bus section would be closed. The only contact that would then remain open in the d-c circuit of the bus scheme would be that of the overcurrent relay in the station neutral. Since these contacts close for a fault anywhere on the 22-kv system an incorrect operation of the bus protective scheme could result.

2. The bus protective scheme for a section would be inoperative if a breaker on a ground source circuit were in the closed position while its isolating disconnects were open. This is a situation that might arise while doing maintenance work on a breaker. If a bus ground fault should occur during this period, the ground directional relay on the circuit out of service could not close its contacts. This limitation of the bus scheme can be overcome by by-passing the *b* switch of the breaker on which maintenance work is being done.

3. The bus scheme of any section is inoperative while any of its relays is being tested. This, of course, applies to any bus scheme but with this one there are a greater number of relays to be tested than on a conventional scheme, and therefore more time is required.

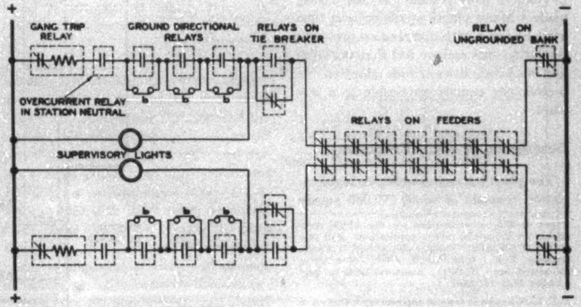

Figure 3. Schematic diagram of d-c relay connections for bus sections 1 and 2

4. This bus scheme does not operate if a bus fault starts as a phase-to-phase or three-phase fault or if a one wire-to-ground or two wire-to-ground bus fault changes to a three-phase fault in less than about one cycle after its start.

Staged Ground-Fault Tests

The various relays of the described bus scheme were installed and put in service in May 1939, but the trip circuits on the gang trip relays were left open temporarily. The purpose of this precaution was to determine, in actual operation, whether any of the relays would operate incorrectly on switching surges or external faults. During this period various disturbances occurred outside the four bus sections during which all the relays of the bus protective scheme performed correctly.

On May 12, 1940 a series of staged ground fault tests were made on each of the four bus sections and on circuits off the various bus sections. In each case the protective scheme operated correctly. Each of the bus faults was cleared in about seven cycles.

Operating Experience

Since May 12, 1940 when the bus scheme was put in service, there have been nine faults on circuits off the bus, and one fault on bus section 4.

The bus scheme was blocked correctly in all cases of faults off the bus.

The fault on the bus, which occurred on the bus side of the breaker bushings marked with the letter *A* in figure 1, was cleared in eight cycles through the operation of the bus protective scheme.

The record of the automatic oscillograph indicates that the disturbance started as a phase 3-to-ground fault. This condition remained for four cycles and after that the fault spread into a two wire-to-ground fault, involving phases 2 and 3.

Conclusion

The bus protective scheme has been applied to an important and rather complicated section of the system, where relatively large generators and power transformers are connected to the busses. Operating experience indicates that the reliability of this bus scheme is not adversely affected by either the magnetizing inrush currents of the power transformers or by the d-c component of the asymmetrical fault currents.

A Distribution System for War-Time Plant Expansion

J. L. McKEEVER
ASSOCIATE AIEE

Introduction

INDUSTRIAL distribution systems to meet the needs of expanding plant facilities for war and defense production are a very live issue today, both in Canada and in the United States. A great deal has already been written on the subject in a general way, as a guide to the proper tailoring of plant distribution to the type of plant and plant production. The purpose of this paper is not to generalize, but to offer a short description of the distribution system installed in the recently expanded facilities of the Peterborough plant of the Canadian General Electric Company, with reasons for the choice made. Many plants at the present time must be faced with distribution problems similar to ours and we feel that our solution has possibilities of wide adoption. It is obviously equally applicable to a new plant.

Description of Plant Extension

The plant extension now nearing completion consists of some 370,000 square feet of floor space in two single story buildings. One building of some 245,000 square feet was constructed to manufacture specialized mechanical equipment while the second building of 125,000 square feet area is to house our wire and cable manufacturing department. They will be designated in this paper as building *A* and building *B* respectively.

The types of load in the two buildings are quite different. In building *A* there will be a connected load of approximately 6,000 hp consisting very largely of small machine tools, plus 900 kva for heating and lighting, while in building *B* with a connected load of approximately 2,500 hp there are an appreciable number of motors in the order of 50 to 200 hp driving rubber mills, Banburys, strainers, etc.

Existing Distribution System

In laying out a distribution system for the new buildings the first thought naturally was to continue with the present system. Power is obtained from four sources, i.e.

Two small hydroelectric stations owned by the company

One steam turbine generator in the company's steam heating plant

Peterborough Utilities Commission

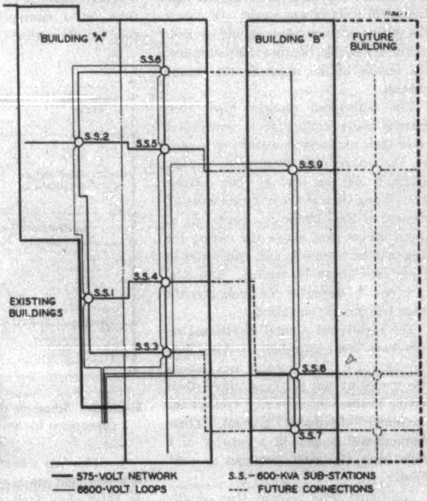

Figure 1. Approximate location of substations in buildings, showing 6,600-volt and 575-volt interconnections

Paper 41-136, recommended by the AIEE committee on industrial power applications, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 16, 1941; made available for preprinting May 15, 1941.

J. L. McKEEVER is general engineer with Canadian General Electric Company, Ltd., Peterborough, Ontario, Can.

Grateful acknowledgement is made of the help given in the preparation of this paper by G. R. Langley, chief engineer, and F. A. Athney, switchgear engineering department, Canadian General Electric Company, Peterborough Works.

1. For all numbered references, see list at end of paper.

While the installation requires a greater number of relays than conventional schemes, it avoids the use of additional current transformers and is independent of the current transformer ratios and characteristics, and can therefore be more readily applied to old stations. Economically it compares very favorably with other schemes.

The protective scheme as installed is practically foolproof. Mistakes made while working on the individual relays or on the various current circuits are not likely to operate the bus scheme. Troubles in the secondary wiring or the relays are more likely to prevent the scheme from operating than to cause an incorrect operation, a condition which is desirable from a system operating standpoint.

These sources are paralleled in the switch room of the steam plant and from there power is fed by 6,600-volt underground cables to four strategically located step-down substations. From these stations the existing plant of 790,000 square feet floor area is fed by conventional radial feeders at 575 volts for power and 115/230 volts for lighting.

Distribution Requirements

If the same radial type of distribution were to be used for the new buildings it was obvious that at least two new substations would be required and, considering the large area to be covered, it would be necessary to decentralize the 115/230-volt lighting transformer capacity by placing a number of small single phase units, either Pyranol or air cooled, throughout the buildings. This is of course in line with the best modern practice and the primaries could readily be connected to the 575-volt radial power distribution system, but there were other more serious problems to be solved.

While the load in building *B* both as regards amount and location was fairly well fixed before construction started, the situation with regard to building *A* was quite different. Here, for a variety of reasons, the final total of connected load could not be estimated at all closely and the layout was undergoing continual changes. Furthermore, due to the fact that the work for which this building was being erected was of a temporary nature, the distribution had to be laid out so that the building could be converted readily to a quite different type of manufacturing. In addition all concerned were interested in keeping costs to a minimum consistent with the conditions to be met.

Proposal

Mr. G. R. Langley, the chief engineer of the Peterborough Works, proposed the use of a number of unit substations with the primaries of the transformers connected into a 6,600-volt loop or ring main, and with the 575-volt secondaries interconnected to form a network. The lighting also was to be decentralized with the lighting transformer primaries supplied from the network. This scheme was adopted as a cost analysis showed that it would reduce the first cost and offer other advantages. While the idea of using a low voltage network for industrial distribution is not new, we believe that the scheme proposed has novelty in the use of the primary loop combined with a secondary network with simplified protection. Actually it is an adaptation of the primary network idea as propounded some years ago by Mr. D. K. Blake and others of the General Electric Company.[1] A recent paper[2] pointed out that an industrial network must differ from the well-known 120/208-volt metropolitan type of network in that with the former, secondary cable faults cannot be allowed to burn themselves off. Thus protective means must be employed at each end of each secondary tie. The network diagram accompanying the above-mentioned paper[2] showed the network ties used simply as ties and protected by fuses or current limiters. The power feeders were taken off busses through air circuit breakers and network protectors were used between the busses and the transformers. Our system is admittedly not designed for uninterrupted service due to tie faults and simplifications were made in using the ties themselves as busses protected at each end by air circuit breakers and omitting the network protectors. So far as we are aware no similar system is at present in use in Canada or in the United States.

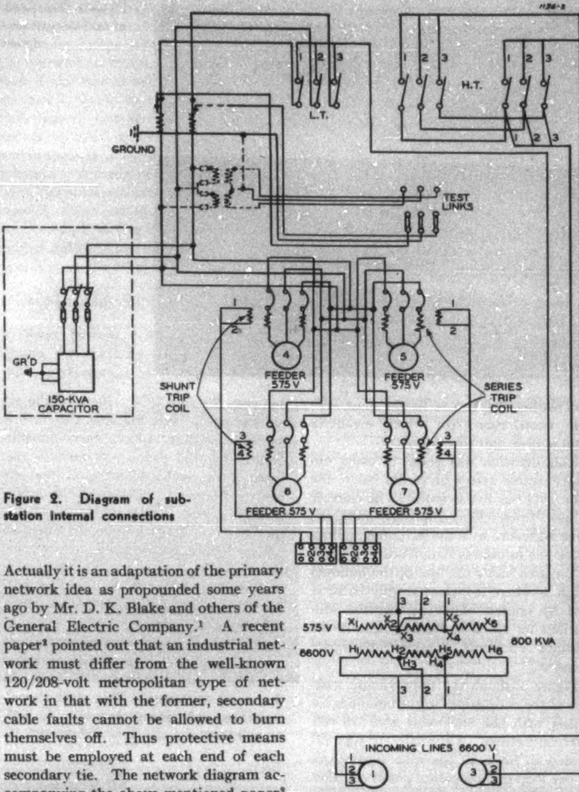

Figure 2. Diagram of substation internal connections

Evolution of Distribution System

Enquiries among other plants and at one plant in particular which had about the same type of load and approximately the same proportion of lighting, electric heating, and power load as we anticipated in building *A*, showed that we might expect a load factor of close to 50% and a power factor of between 70 and 75%. With a radial distribution system, allowance for growth and spare capacity would have necessitated the installation of about 4,500 kva in transformers for building *A* and between 2,000 and 2,500 kva for building *B*. With the network and loop system however, the ease with which a future additional substation can be connected into the system, together with its load dividing properties enables a considerable saving in transformer capacity. Incidentally this feature dispenses with one of the bug-bears of consulting engineers, namely the difficulty in drawing a mean between risk and over-conservatism in deciding upon transformer capacity. The capacity decided upon in our particular case was 3,600 kva for building *A* and 1,800 kva for building *B*. Investiga-

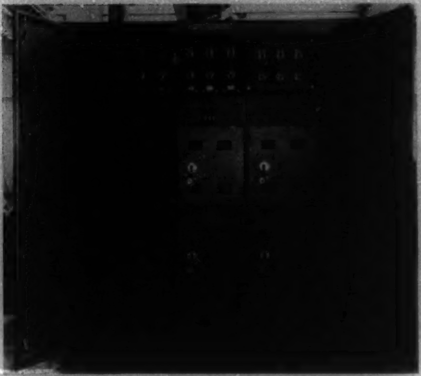

Figure 3. Front view of 600-kva unit substation

tion showed 600 kva to be the most suitable transformer size which meant a total of nine unit substations.

Consideration was given to using oil-cooled transformers in vaults below the floor level but it was found to be cheaper to use Pyranol filled transformers in the same enclosure with the switching. Floor space has minimum manufacturing value in the area along the line of the building columns where it cannot readily be serviced by cranes. Thus placing the substations on the floor backed against the columns represents no appreciable waste of space.

Figure 1 shows the approximate location of the substations in the buildings together with the 6,600-volt and 575-volt interconnections. Originally it was intended to have all the nine substations on one loop but a separate power contract for building *A* made it necessary to have two loops. This works out quite well however, as the wire building loop allows for the addition of three more substations in a future building alongside it so that actually the 6,600-volt cables for the two loops are identical.

The 575-volt switching in each station consists of four 400-ampere air circuit breakers of the dead-front type mounted two high as shown in figure 3. A low tension hook-operated disconnecting switch is provided for disconnecting the transformer from the air breakers, as shown on the top right of figure 3, while the two disconnecting switches appearing at the top left and centre permit the isolation of any section of the loop cable and also serve to disconnect the high voltage side of the transformer from the two ends of the loop.

It was mentioned earlier that the power factor to be expected in building *A* was between 70 and 75%. Each of the six substations in this building therefore is provided with a 150-kva capacitor controlled by the dead-front quick-break, fused knife switch showing at the left centre of figure 3. This is all the equipment provided in the substation except for one current transformer and some test links. Figure 2 shows the connections for the complete substation. The three substations in building *B* are identical with those in building *A* except for the omission of the capacitors.

Various designs of substation structure were considered and the final decision was to enclose transformer and switching in the same enclosure. This arrangement tends towards compactness as is evidenced by the dimensions which are 7 ft. 8 in. width, 8 ft. 6 in. depth, and 8 ft. 4 in. height. All wiring in the building for the 6,600-volt loop and the 575-volt network is overhead and the conduits are brought down the building column and through the roof of the substation.

Figure 1 shows the 575-volt interconnections between stations and the various stub feeders. From junction boxes, taps are taken to 50-kva single-phase Pyranol filled lighting transformers and to GE Trumbull Swing-Wa power panels. In one case in building *B* where a number of controls for large motors are placed in an enclosed force-ventilated control room, two runs of Trumbull Flex-a-power are used between the substations these runs passing through the control room, and connections for the controls are made to them.

Protection

Considerable study was given to the protection of this distribution system against faults in any part of it. Experience with our present system has shown that faults are extremely rare in the 6,600-volt cables and transformers, and this in conjunction with the fact that the rare short interruption of power is not particularly serious with the type of manufacturing involved, permitted simplified protection. The oil circuit breakers at either end of each loop are equipped with inverse-time induction type relays with instantaneous attachments. The loop cables are large enough to feed all stations on the loop from one end, and as already mentioned, disconnecting switches are

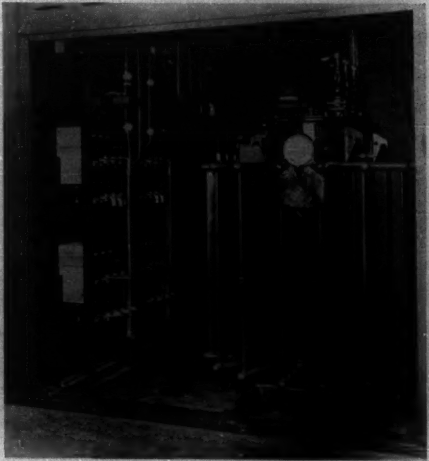

Figure 4. Internal view of 600-kva unit substation showing transformer, capacitor rack, and air circuit breakers

provided at each station so that any section of cable may be isolated. A temperature detector in the transformer winding will ring an alarm upon any serious temperature rise and should it become necessary to remove a transformer for examination or repair before a major fault develops, it can be removed from service without dropping load except on the stub feeders, by the following routine:

1. Trip the four 575-volt air circuit breakers to remove load from the transformer.
2. Open the loop disconnecting switches.
3. Open the 575-volt disconnecting switch and disconnect the transformer high tension leads.
4. Reclose the loop disconnecting switches and the four air circuit breakers.

An actual fault on either transformer or loop cable will open the loop oil circuit breakers and interrupt power for a short period but, as already mentioned, the inconvenience of such a shut-down does not, under our conditions, justify guarding against it.

Figure 5. General view showing small space occupied by 600-kva unit substation

The air circuit breakers in the network are provided with combination inverse-time and instantaneous overload trips which will give adequate selective protection. Calculations of fault currents have been made which indicate the maximum short-circuit current from all six stations at the terminals of any one of the air circuit breakers to be within safe limits. They also show the possible currents at the load side of the Swing-Wa power panels to be within the known tested rating of the standard cartridge fuses used. Actually the calculated fault currents are sufficiently low to allow considerable expansion beyond the six stations and indicate the feasibility of networks of larger capacity with the same standardized design of unit substation.

To provide peak load control, which may or may not be generally required, the network air circuit breakers are provided with shunt trips and a multi-conductor control cable is run from the operating room in the steam plant, allowing the operator to dump any section of the load if the contracted ten minute peak demand is liable to be exceeded. The stub feeders can obviously be disconnected without disturbing the network and in the case of the wire building where mention was made of two 575-volt network ties running through the large motor control room, one of these can be disconnected at each end dumping half the rubber mills but leaving the other half in operation on the other tie.

Direct-Current Supply

Direct current power is usually required for operation of cranes, boring mills, and certain other machines. In our case this power is supplied by motor-generator sets the induction driving motors of which are supplied from the network. With the load dividing feature of the network system such motor-generator sets can be connected into any convenient point close to the machines to be supplied without the prior thought necessary with radial feeders.

Comparison of Costs

In making a cost comparison between the network system described above and the radial system we would otherwise have installed we were fortunate in having access to the actual cost of a radial system recently installed in an Ontario plant of floor plan and area similar to building *A* in our plant. With the radial system the transformer capacity for building *A* alone would have been at least 4,500 kva and the costs from the other plant have been adjusted to this capacity. On this basis the network system showed a saving of $18^1/_2\%$.

With the present radial system in our plant it has been the practice to use reduced voltage starters on all squirrel-cage induction motors of 50 hp and larger. The excellent voltage regulation characteristics of the network system, however, made reduced voltage starters unnecessary and the omission of these brought the saving with the network system to $22^1/_2\%$, representing a figure in excess of $22,000 for building *A* alone.

Conclusion

The saving in capital expenditure realized by the use of the network system just described is sufficiently attractive in itself, but when this saving is coupled to the many other advantages the system offers, there seems to be good reason to expect its wide adoption.

Many plants in these days are faced with expansion problems similar to ours and it is hoped that our experience may be of value to others. The flexibility of the network system for increasing loads was impressed upon us recently by difficulties encountered with one of our existing radial substations in which the power transformer bank was seriously over-loaded. This substation had been built to take care of what at the time was thought to be ample future growth but it is now inadequate both in installed capacity and space for extension. In order to relieve the overloaded transformer bank it was necessary to split the 575-volt bus and feed part of it from a small transformer bank of incorrect characteristics for paralleling located in the test department substation several hundred feet away. Had we had a system similar to the one in our new buildings it would have been an easy matter to build another unit station and to connect it into the 6,600-volt loop and the 575-volt network.

The saving in transformer capacity, the saving in reduced voltage starters due to the good regulation, the high salvage value of equipment, and the simplicity of protection with the low-tension network and high-tension loop system of distribution have already been mentioned. These merits should assure its wide adoption in industrial plants.

An Improved Frequency Meter for Commercial Power Frequencies

K. J. KNUDSEN
MEMBER AIEE

Synopsis: While frequency meters of prior type admirably serve the purpose for which they are intended, their construction has been such as to necessitate the use of an external reactor. This external reactor is in most cases not objectionable, but for certain applications, where space is at a premium, a self-contained instrument is preferable.

This paper describes a frequency meter in which the external reactor has been eliminated by using an iron-core cross-coil instrument, the iron core serving the purpose of the normally external inductance, at the same time shortening the high reluctance air gap necessary for the moving coils.

Introduction

USING an iron core greatly reduces the ampere turns necessary to establish an adequate field intensity, which is proved by the fact, that while the power necessary to operate frequency meters now being used range from 2.5 to 7.5 watts, depending on the design, this instrument consumes a maximum of 0.8 watt at 115 volts, or one-third the power of the prior instrument using the lowest power.

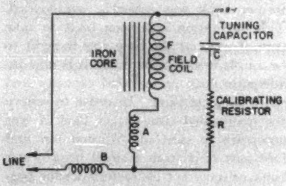

Figure 1. Schematic diagram of frequency meter

While the power consumption in most cases is insignificant with respect to the loss, it is important that a self-contained instrument use no more power than can be readily dissipated within the confinement of the case. Low power loss also simplifies compensation, as there is little change in temperature from the moment the instrument is energized till the temperature of the coils have reached constancy. In a self-contained instrument compensation is further simplified, because all components are mounted within the same container and therefore exposed to the same ambient temperatures, while if an external reactor is used, means must be provided to compensate for a possible difference of the temperature of the instrument proper and that of the reactor.

Theory

Referring to figure 1, the moving coil A is connected in series with the field coils F and therefore tends strongly to align itself with the magnetic flux in the air gap, the current through the coil being in phase with the flux. The capacitor C in series with the compensating resistor R, causes the resultant current in moving coil B to be 90 degrees out of phase with the air gap flux at the frequency corresponding to the center point of the scale. As the frequency varies from the center scale value, the power factor of the current in coil B will change, due to the altered impedance ratio between the field coils and the capacitor, resulting in a clockwise or counterclockwise deflection of the pointer, as the frequency increases or decreases.

As the power factor of the field coils, in series with coil A, is approximately 25 per cent, and the power factor of the current through coil B is about 97 per cent, four times as many turns, of correspondingly smaller size, may be used in coil B than in coil A for an equal heat loss in the two moving coils, resulting in a high order of deflection for a small change in power factor of the current in coil B.

The iron core is made from laminated "47-50" nickel iron due to its high resistance to corrosion and ease of stamping. Damping is provided by an aluminum vane moving through a strong unidirectional magnetic field established by an Alnico magnet.

Comments on Accuracy

The primary function of a frequency meter is, as the name implies, to indicate the frequency of an a-c circuit. Many causes tend to give an indication differing from the actual frequency, the most important of these are: Fluctuation of the line voltage, ambient temperature changes, and distortion of the voltage wave of the circuit.

Compensation for voltage influence has been accomplished by a high ratio of torque caused by the current flowing through the moving coils, to the torque of the ligaments connecting the moving coils to the stationary circuits. Figure 2 is a graph showing the voltage errors from 90 to 140 volts.

While conducting tests for voltage error on a number of instruments, some instruments would indicate erratically when high voltage was applied at certain frequencies. It was found that the two ligaments at one end of the moving coil assembly would short-circuit due to vibration of one of the ligaments, the vibration being set up by interaction between the magnetic flux in the air gap and the current through the ligament. The difficulty was overcome by cutting a turn of the ligament, thereby increasing its natural vibratory frequency above the measuring range of the instrument.

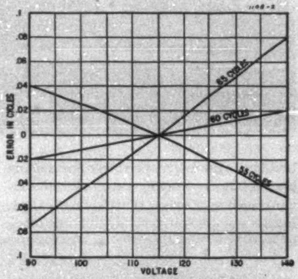

Figure 2. Voltage error curves

There are two main reasons for errors due to ambient temperature changes, they are: Resistance changes of coils and capacity changes of the capacitor used for tuning the field. In order to offset these errors, which have to be compensated simultaneously, a high temperature coefficient resistor is connected in series with the capacitor, thereby maintaining a constant phase relation between the current in the deflecting coil B (figure 1) and the magnetic flux in the air gap for a given frequency, at varying ambient temperatures.

It is important that a high-grade capacitor be used for an instrument, the purpose of which is to indicate small changes of reactance due to frequency changes.

Paper 41-108, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16-20, 1941. Manuscript submitted August 23, 1940; made available for preprinting May 5, 1941.

K. J. KNUDSEN is chief engineer of Hickok Electrical Instrument Company, Cleveland, Ohio.

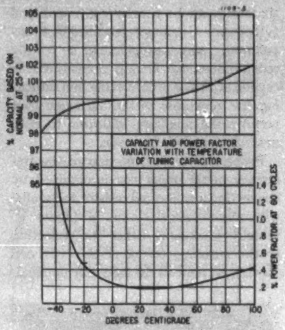

Figure 3. Capacitor-temperature capacity and temperature-power-factor curves

If considerable change of capacity would be caused by normal changes in ambient temperature, the instrument would be worthless as a frequency indicator; for this reason an oil-filled capacitor has been used, which has low and almost uniform temperature coefficient of capacitance within the normal range of temperatures. Figure 3 shows the capacity-temperature curve of the capacitor, and in addition the power factor-temperature curve. It will be noted that the power factor is almost constant within the measuring range, thus aiding the stability of the circuit.

As the temperature coefficient of capacitance is positive, it partly offsets the tendency of the instrument to read high at high temperatures, due to the increased resistance of the copper coils in the field circuit. Satisfactory compensation can be obtained between minus 20 and plus 45 degrees centigrade, by using a resistor in series with the capacitor, the temperature coefficient of the resistor having been adjusted to offset the combined causes tending to give an erroneous reading due to changes in temperature. Figure 4 shows the temperature error before and after compensation. While the capacitor has been under observation for a year, no change of capacity due to aging has been detected; it is however felt that insufficient time has passed to give exact data on aging characteristics.

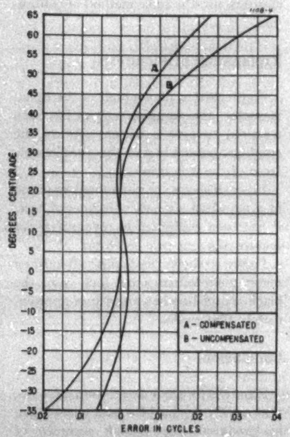

Figure 4. Temperature error of frequency meter

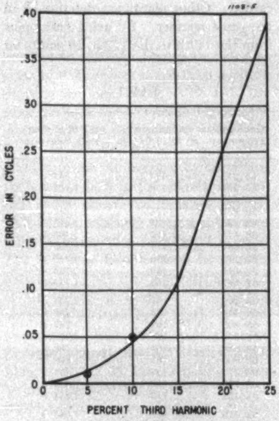

Figure 5. Third harmonic error

As the inductive reactance of the field circuit increases proportional to the frequency, and as the deflection of the pointer is caused by interaction between the moving coils and the magnetic flux of the field circuit, it will be seen, that the lower the harmonic present in the voltage wave, the greater is the tendency to indicate erroneously. Tests have been conducted to determine the effect of the third harmonic on the accuracy of the instrument, because this harmonic is the lowest commonly encountered in commercial supply lines. Figure 5 shows the error caused by varying magnitudes of third harmonic; changing the phase relation between the fundamental frequency and the third harmonic through 120 electrical degrees had no appreciable influence on the error indicated.

While the third harmonic influence seems rather high, it should be realized that the third harmonic, which is generally introduced into the voltage wave by the excitation of iron-core equipment due to the increased current at high saturation, seldom exceeds five per cent.

A four per cent seventeenth harmonic tooth ripple, present in the voltage of the generator used for calibration, had no influence on the accuracy, the indication being the same after eliminating the ripple by means of tuned by-pass filters.

Calibration

In order to obtain accurate calibration of the instrument without waste of time a multivibrator was used, having steps of 87,480, 29,160, 9,720, 1,620, 540, 180, and 60 cycles. The multivibrator is crystal controlled to one cycle in five million, its accuracy ascertained by comparing the time indicated by a synchronous electric clock, connected to the 60-cycles output stage, with radio time signals.

While the method of determining one frequency by its harmonic relation to another is not new, it is felt that it has been limited to a ratio, where it was possible to count the loops on the screen of the oscillograph. In the case where the harmonic ratio is more than 150 to one, counting the loops would be impossible without auxiliary means; a detailed description is therefore given of the method of calibration.

The instrument is calibrated by connecting the horizontal sweep circuit of an oscillograph to the 9,720-cycles stage of the multivibrator, and the vertical sweep to the variable speed generator used for calibration, the vertical sweep being amplified to extend beyond the limit of the screen, so as to show only two or three loops of the horizontal sweep, as indicated in figure 6.

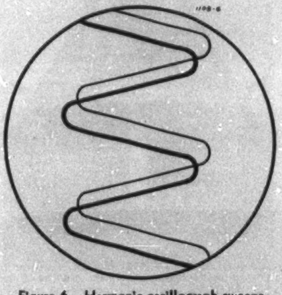

Figure 6. Harmonic oscillograph sweeps

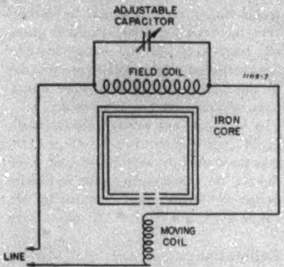

Figure 7. Schematic diagram of auxiliary frequency meter

As the frequency of the multivibrator is the 162nd harmonic of 60 cycles, some means must be employed to determine that the proper harmonic is used, there being only four-tenths cycle approximately between harmonics as compared to 60 cycles. A high-resistance voltmeter is connected in series with the 60-cycles stage of the multivibrator and the variable speed generator. The generator is adjusted until a steady reading equal to the sum of the voltages of the two supplies is obtained on the voltmeter. This reading is only obtainable when the voltages are synchronous and 180 degrees out of phase, the harmonic indicated on the screen must therefore be the 162nd.

In order to keep track of the harmonics used for calibrating the scale, an auxiliary frequency meter is used. The basic circuit of this instrument, shown in figure 7, is the same as that of the instrument under test, except that the restoring torque is provided by springs; the instrument is therefore accurate at only one point of the scale, the deflection at other points being dependent on the line voltage. An adjustable capacitor is used for adjusting the auxiliary instrument to center scale when the proper harmonic is found, by means of the voltmeter, at 60 cycles. As the sensitivity of the instrument is in the order of one-tenth cycle for full-scale deflection, it will be completely off scale if a wrong harmonic is used for calibration, and exact adjustment to center scale is therefore not necessary.

After the auxiliary instrument has been calibrated to 60 cycles, the setting of the adjustable capacitor is recorded and the speed of the generator is then slowly changed until the next harmonic appears on the screen. The auxiliary indicator again adjusted to center scale and the setting of the adjustable condenser recorded. Other points are determined in the same manner. By using harmonics from the 149th to the 177th, 29 points on the scale can be exactly calibrated and actual scale divisions determined by interpolation. Any harmonic can be readily redetermined by setting the adjustable capacitor to the proper value and adjusting the generator to the harmonic that permits the auxiliary indicator to read near the center of the scale.

Table I

Generator Frequency	Subharmonic of 9,720 Cycles	RPM of Four-Pole Generator
54.915	177	1,647.5
55.227	176	1,658.8
55.543	175	1,666.3
55.862	174	1,675.9
56.185	173	1,685.5

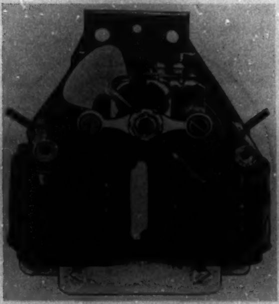

Figure 8. Frequency meter dynamometer

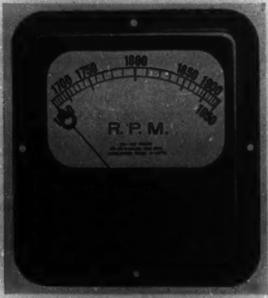

Figure 9. Frequency meter in six-inch case

Proper full-scale deflection of the frequency meter under test is obtained by connecting a calibrated resistor in parallel with either coil *B* or coil *A* (figure 1), thereby weakening either the deflecting or the restoring torque of the cross-coil moving element as the case may demand.

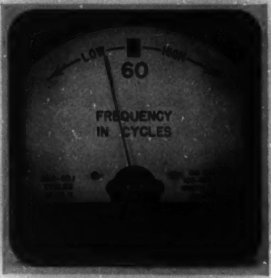

Figure 10. Auxiliary frequency meter in five-inch case

Table I shows the frequency and speed in revolutions per minute of a four-pole generator corresponding to the harmonics being used for calibration, it is included for the convenience of those, who may desire to use the same method of calibration.

Explanation of Pictures

Figure 8 is a photograph of the dynamometer; the damping magnet has been removed to give a better view of the cross-coil assembly and the parallel pole faces of the iron core.

Figure 9 shows the instrument mounted in a standard six-inch switchboard case, it has been calibrated in revolutions per minute of a four-pole generator.

Figure 10 shows the auxiliary frequency meter mounted in a five-inch case, the black center line has a width of approximately 0.01 cycle.

Conclusion

From the foregone description it is seen, that a self-contained frequency meter can be produced, the over-all accuracy of which is better than two-tenths cycle in 60 cycles, permitting a third harmonic

Mechanical Simplicity of Air-Blast Circuit Breakers

H. W. HABERL
ASSOCIATE AIEE

OTTO JENSEN
ASSOCIATE AIEE

THE papers heretofore presented before the Institute on the subject of air blast circuit breakers have covered primarily their advantages in comparison with oil circuit breakers, the principles involved in current interruption by air blast, descriptions of interrupters developed by several manufacturing companies, the results of tests and related data. It is considered opportune to give an account of several other types of air blast circuit breakers ranging in voltage from 4 kv to 230 kv as developed and built by certain manufacturing companies in Canada and the United States in collaboration with a large power company. The first machine of this general type was a 138-kv air blast breaker placed in service in 1934 at the Beauharnois generating station on lines to Montreal, this breaker having continued in service for six years successfully interrupting all faults; three additional breakers of the same general design with improved details have been placed in service at this station in later years.

Breakers of four types built by three manufacturing companies, all breakers having certain general features in common, will be illustrated by photographs and diagrams. In all of the breakers described, the general design of interrupting contacts is the same. This arrangement of contacts is suitable for the use of arc chutes utilizing any one of the elementary principles of pneumatic arc extinction or combinations of such principles.

Types marked "A" include breakers for 138 kv and 230 kv built by the English Electric Company of Canada.

Types marked "D" are 69-kv breakers built by the same company.

Types marked "B" are breakers of 15 kv to 37 kv built by the I-T-E Circuit Breaker Company, in Philadelphia.

Types marked "C" are breakers of 4 kv to 15 kv built by the Eastern Power Devices Limited, in Toronto.

The diagrams of each type are numbered 1 to 7 to show the sequence of operation.

Type "A"

Photograph *A* shows one of the 138-kv breakers in service. Figure 1*A* is a diagram of this breaker in the open position showing the main parts which are: the tank storing air at 100 lbs. per sq. in., the interrupter, and the isolating switch. In figure 2*A* the closing coil is being energized to close the breaker by admitting air from the tank to the cylinder and piston which closes the isolating switch. This coil is extremely small and becomes fully energized in a fraction of a cycle. The coil only has to move its plunger about one-eighth inch uncovering a port of one-eighth inch diameter, releasing about one-quarter cubic inch of compressed air from under a rubber diaphragm of about two inch diam. which is blown open by the opposing air pressure on the other side, thus opening the valve which admits air from the tank to the isolating switch cylinder and closes the switch. The cylinder of each pole is mounted under the bedplate of the interrupter, at line potential, as close as possible to the switch blade operated by a short link. Electrical, pneumatic, and mechanical inertia are reduced to the practical limit thus minimizing the closing time. A standard auxiliary switch to perform the usual functions, is operated from the isolating switch blade by a 90-degree rotation of the same porcelain tube (of one inch inside diameter) conveying closing air to the switch cylinder. Provision is also made for raising and lowering this porcelain tube one inch, to perform additional functions in connection with quick automatic reclosing.

The jaw contacts of the isolating switch are mounted on the cap of the porcelain cone of the current transformer; this cap is purposely made extra heavy in weight and is supported on rubber bushings to minimize mechanical shock to the porcelain due to fast operation of the switch blade. The jaws are full-floating and swivel to facilitate cracking of ice film in opening; a large sleet hood also covers the contacts.

The interrupter has three identical interrupting elements in series in the 138-kv breaker and six in the 230-kv breaker. Each element has two stationary contacts bridged by one movable contact thus making two breaks in series per element. The movable contact is rigidly secured to a steel piston rod and piston working in a bronze cylinder insulated from adjacent cylinders. Figure 3*A* shows the breaker in the closed position.

As shown in the photograph *A*, the 138-kv breaker has one tank and three blast valves. The 230-kv breaker has three separate tanks to facilitate shipping and erecting the greater length. The 230-kv breaker is built up with the same parts as the 138 kv and almost all of the parts are interchangeable. Due to the greater height, the 230-kv interrupter is brazed with diagonal stacks of standard switch insulators.

The blast valve which is the same for 230 kv and 138 kv, is built into the side of the tank with an inlet of about three square feet section. The outlet of the valve is a funnel-shaped orifice of about 8″ diameter at the valve seat which is normally closed by a thick rubber diaphragm about 20″ diameter, reinforced by a light steel disk vulcanized to the rubber. The diaphragm moves down about one inch to fully open the valve. Air pressure at 100 lbs. is maintained underneath this diaphragm, to hold it closed. The volume of air under the diaphragm is less than one-twelfth of a cubic foot. To open the breaker this small volume of air is exhausted to atmosphere by two or three one-inch diameter orifices each normally held closed by a diaphragm and coil of the same size as

---

distortion of ten per cent, a voltage fluctuation of 90 to 140 volts, and an ambient temperature range of minus 10 to plus 40 degrees centigrade. The power consumed being eight-tenths volt-ampere at 97 per cent power factor.

As the complete instrument can be installed in a $3^{1}/_{2}$-inch case, it is well adapted for use where space is limited. The elimination of an external reactor reduces the work involved in wiring and installation.

High-voltage air-blast breaker

For this type of breaker there are three interrupting elements in series, each individually air-operated

that described in connection with the valve used for closing the isolating switch. The weight of the moving parts of the blast valve is small, less than 5 pounds and the accelerating force is about 10,000 pounds, which gives an acceleration of about two thousand times that of gravity. This accounts for the very fast opening of these breakers, about one-sixtieth of a second from energizing the trip coil until parting of contacts, which of course is fast for a breaker of this large size. The interrupting element also contributes to this short opening time, the moving part having a weight of less than ten pounds and an accelerating force of about 2,000 lbs.

Figure 4*A* illustrates the conditions during the opening of the interrupter. The blast valve is open; a wave of air pressure is travelling up the porcelain blast tube, compressing the atmospheric air standing in the tube and header in the interrupter structure, similar to a sound wave, blasting the interrupter pistons to the left, opening the contacts and interrupting the arcs. A pressure wave is also travelling through a half inch pipe to the isolating switch cylinder but it cannot reach the cylinder in less than several cycles, leaving ample time for the interruption of the arcs before the isolating switch parts contact. This is shown in figures 5*A* and 6*A*.

Low-voltage air-blast breaker

In this type of breaker the main blast diaphragm operates the three phases of the interrupter elements

As the isolating switch is almost fully open, its auxiliary switch opens the trip circuit and the spring in the trip coil closes the trip valve permitting the reestablishing of pressure under the blast valve diaphragm by the flow from the tank. It has been found unnecessary to provide an area under the diaphragm greater than the area on top of it in order to make the diaphragm reseat, because there is an ejector effect which reduces the pressure near the center of the diaphragm due to the high velocity of the discharge and the diaphragm reseats promptly when the trip circuit is opened. Means have been developed for automatically shutting off the infeed of air from the tank to the lower side of the diaphragm while exhausting that space through the trip valve, but in service it has been found that satisfactory timing is obtained without such device. In general, the breaker can be blasted several times in quick succession before the tank pressure is reduced below the safe operating limit. When several breakers are installed in the same station, a common auxiliary storage tank is provided which quickly restores pressure in the breaker tank after which normal pressure is restored in the storage tank by the automatic starting of the compressor.

The 230-kv and 138-kv breakers are well adapted to single pole operation as there is no mechanical connection between poles. The switchboard operator can change the control from three-pole operation to single-pole operation by simply turning a control switch.

Type "B"

Photograph *B* illustrates a 35-kv breaker built by the I-T-E company which has been in successful service outdoors in New England for about two years at a location near the seashore where the salt spray constitutes a test of insulation even more severe than the St. Lawrence River mists on the higher voltage breakers. Figure 1*B* is a diagram of this 37-kv breaker in the open position. The interrupter has only one moving contact per pole; it is rigidly secured to a steel piston-rod and piston moving vertically in a cylinder which is at line potential. There is one blast valve and tank serving the three poles. The blast valve outlet divides three ways inside the tank and the three tubes pass through the tank to their respective poles. The blast valve is of the same general design as that of the higher voltage breakers, with certain modifications in detail, including springs to accelerate reseating of the diaphragm. The three poles of the isolating switch are operated by one cylinder at ground potential.

Figures 1*B* to 7*B* show the sequence of operation of this breaker. All breakers described in this paper are equipped with a pneumatic trip-free device operated by blast pressure to shut off compressed air supply to the closing end of the isolating switch cylinder and exhaust the air trapped in the closing end. The exhausting action is accelerated by the ejector effect of the nozzle in case the isolating switch closes on a short circuit.

Breakers of this same type also have been built by this company for 15 kv and 3,000 amperes. The current-carrying contacts are separate and part slightly before the interrupting contacts, all being rigidly fastened to the same operating piston-rod. In these breakers means are provided for surrounding the stationary contacts by air pressure to prevent premature parting of contacts before the moving contacts have moved away.

Type "C"

Photograph *C* illustrates a type of smaller breaker for 15 kv to 4 kv indoor service, 2,000 amperes, built by the Eastern Power Devices Limited. The main distinguishing feature of this type is the method of operating the interrupter contacts. The blast valve is of the same general design as in the other breakers except that the diaphragm has secured to its center, a steel operating tube which is rigidly connected to the interrupting contacts of the three poles through an insulating rod in each pole. When the valve diaphragm moves down it opens the blast and also mechanically opens the interrupting contacts. In order to insure that the contacts do not part before the blast arrives to interrupt the arc, a slight amount of slack is provided between the valve diaphragm and the operating rod so that the diaphragm moves down opening the valve part way before beginning to move the contacts. To minimize shock on the moving parts in opening, a spring is inserted between the diaphragm and operating tube.

Floor space is minimized by placing the tank vertically on end, the blast valve constituting the lower end of the tank. The blast valve outlet is shown in the diagrams as a single tube but actually it divides three ways passing up through the tank and out the top end of the tank in equilateral triangular formation; each of the three vertically projecting blast tubes is a 4″ standard pipe welded to the top of the tank and acts as the support for one pole of the interrupters. Each interrupter pole consists of a vertical cylinder of insulating material, 9″ inside diameter which provides sufficient space for interrupting elements of ample capacity.

Figure 9C. Opening sequence

Figure 10 C. Oscillogram of interruption

A 2,000-amp. breaker of this type has a width of only 2′6″. This design is well adapted to various indoor layouts of stations and cell arrangements, including a draw-out arrangement of eliminating the usual disconnecting switches. This design can also be turned upside down and adapted to go into cells built for the old style oil breakers with live parts at the bottom.

Type "D"

Photograph *D* shows the general arrangement of 69-kv breakers built by the English Electric Company of Canada. It has one blast valve for the three poles, the valve being of the same design as the other breakers described. The blast tube passes horizontally through the tank to the external header tube parallel to the tank, serving the three poles through vertical stacks of porcelain blast tubes. Inside of each stack is an insulating operating rod opening and closing the interrupting contacts of the same design as in the other breakers. Each of these three operating rods is directly connected to a piston at the grounded end and in addition the three piston-rods are mechanically tied together through short links and a common shaft. The three poles of isolating switch blades are operated by a common cylinder at ground potential. The switch blade is a hollow bronze casting enclosing the hinge of a short toggle blade which makes a swiveling engagement with the stationary full-floating jaw contacts facilitating sleet cracking in opening. The blade is side opening facilitating sleet-hood protection and simplifying insulators, only two stacks per pole being required. A simple arrangement of arcing contacts has been found satisfactory in closing on short circuits with negligible burning; the operation of the isolating switch is very fast.

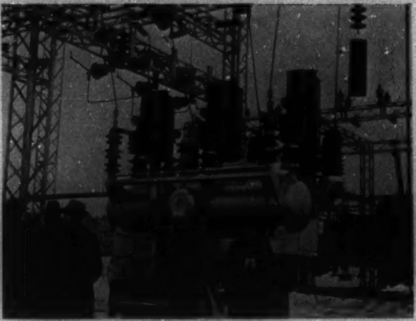

Figure D. General view of 69-kv air-blast breaker

Operating Results

The service record of breakers of this general design dates from 1934 when the first 138-kv breaker was installed. Since that time breakers of the several other voltages have been placed in service and the record is now equivalent to 20 breaker-years of service. The number of breakers recently installed and on order is 30. There have been 15 breaker interruptions reported in service, with no failures.

Interrupting Ratings

The 230-kv breaker is rated 2,500,000 kva; single-pole interrupting tests on sections of this breaker have shown interrupting capacity equivalent to more than 3,000,000 kva on the complete 3-pole breaker. The 138-kv breaker is rated 1,500,000 kva; 69-kv breaker 1,000,000 kva.

Insulation

The standard specifications for breakers of the several voltages are complied with.

Operating Time

The opening time is three cycles or less, from energizing of trip coil to current interruption. Reclosing time is within 20 cycles from energizing trip coil.

Operating Current

Closing coil or opening coil takes ten amperes or less; can be reduced to one ampere.

The Shielding of Permanent Magnets From Transient Magnetic Fields

GEORGE J. WEY
ASSOCIATE AIEE

Introduction

CONSIDERABLE progress has been made toward the development of permanent magnets which are immune to disturbing conditions, such as temperature variation, mechanical vibration, natural aging, and extraneous flux fields. Contributions to this progress include new materials, improved processing techniques, and better manufacturing controls.

Constancy of flux is in most applications quite essential. This is particularly true of electromagnetic damping, in which the damping torque varies as the square of the air gap flux. The permanent magnet of a watthour meter is an example.

Despite the fact that the modern permanent magnet is remarkably stable, there have been cases in which the magnets showed changes in strength, generally becoming somewhat weaker. Isolated instances of such changes in watthour meter magnets have been found by the electric utility companies.

About four years ago, evidence gathered by various utilities pointed to lightning discharges as the probable cause of the demagnetization. After initial laboratory tests failed to demagnetize meter magnets by passing surge currents through the windings alone, it was realized that the demagnetizing field was primarily caused by surge currents in the service wiring itself. Figure 1, curve 1 shows the amount by which forged chrome steel magnets are weakened by a single surge of the value indicated by the abscissa using the test setup shown on the figure 2.

To date, there have been no extensive studies made of the magnitude and frequency of surge currents appearing on the secondaries of distribution systems. Figure 3 shows expectancy curves for lightning discharges in distribution system primary arrester ground leads from the investigations of McEachron and McMorris.[1] These curves show that in rural areas a discharge of 5,000 amperes may be expected at any one arrester location once in 14 years and a 10,000-ampere discharge once in 30 years. In attempting to apply these expectancy curves to the distribution secondaries, however, they should be considered as extremely pessimistic because of the reduced exposure of the secondary circuit.

It is evident from a consideration of the rarity with which high current discharges appear on distribution systems that any program designed to materially reduce the number of weakened magnets found on the system secondary must be applied to a large percentage of the total exposed installations. Thus, it would be desirable to protect not only new meters but also those in service.

Since there are millions of standard forged steel magnets in service, it would be desirable that surge protected magnets should not require new techniques or tools to service them.

High Coercive Alloys

The problem of making permanent magnets impervious to transient magnetic fields has been solved in two ways by the various meter manufacturers. One method has been to make the magnet from one of the new high coercive materials, such as Alnico. The coercive force, H_c, of these alloys ranges from 400 to 600 oersteds which means that when properly applied to a watthour meter such a magnet would withstand surges up to 25,000 amperes without appreciable weakening. Another advantage of these alloys over forged magnet steel is economy of space for a given air gap energy. However, before this advantage can be realized to any appreciable extent, the whole meter must be designed with this object in view. Also, a complete new magnet design must be made and manufacturing processes developed in order to utilize the new alloys.

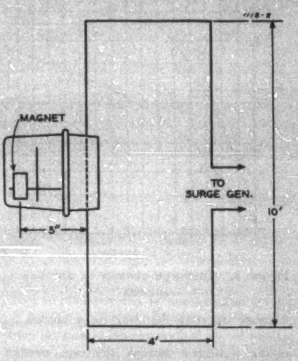

Figure 2. Setup for surge tests on permanent magnets

Electromagnetic Shielding

An alternate solution to the problem of transient fields and the one described in this paper is to use electromagnetic shielding around the existing forged steel magnets. While this principle of shielding is old,[2] it is felt that a description of its application to permanent magnets is new and may be of general interest.

The requirements of an efficient electromagnetic shield are: first, the shield must provide low resistance paths for the flow of eddy currents. Second, the shield must be continuous about the object to be shielded so the eddy currents can flow in any direction.

The above requirements immediately suggest plating the magnets with copper,

---

Paper 41-112, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 23, 1941; made available for preprinting May 7, 1941.

George J. Wey is with Westinghouse Electric and Manufacturing Company, Newark, N. J.

[1] For all numbered references, see list at end of paper.

since copper has low electrical resistance and a continuous sheath of the metal could be easily plated on steel. With the ordinary process of electroplating copper from a copper sulphate solution, however, it is impractical to build up a coat more than 0.002″ thick, and even this thickness requires upward of 24 hours plating time.

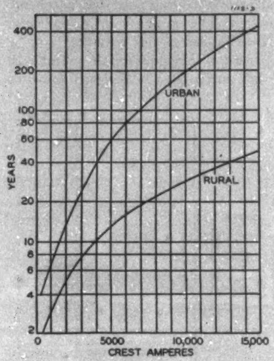

Figure 3. Discharge currents in distribution arresters

Number of years that may be expected to elapse for each discharge of at least the magnitude indicated through any one arrester

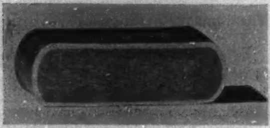

Figure 4. Cross section of plated magnet

Figure 1, curve 2 shows the shielding effect of a 0.002″ thick plated copper sheath using a 24x40 wave (24 microseconds to crest, 40 to half value). By comparing with curve 1 it will be seen that such a shield is quite effective against transients.

Another method of applying a metallic coating is by the Schoop spray process. By this means metallic coatings of any desired thickness can be applied to magnets. Figure 1, curve 3 shows the shielding effect obtained by this method. Due to the porosity and consequent high resistivity of the deposited metal and the difficulty of obtaining a uniform coating, this method was considered inadequate.

Good shielding can be obtained by the use of copper-clad steel made by any of the standard commercial processes. Figure 1, curve 4 shows the shielding obtained from a 0.020″ thick layer of copper formed by the Roth process. This process consists of placing a properly fluxed billet of steel in a vertical mold. After heating the mold and billet to a red heat, molten copper is poured around the billet. The mass is then rolled to the desired bar size. The principal disadvantage of copper-clad steel for magnets is that the conductivity of the copper is lowered during the heat treatment of the magnet steel. Also, the copper coat is not of uniform thickness, which reduces its effectiveness.

High-Speed Copperplating

Early experiments with a new high-speed copper-plating process invented by the E. I. du Pont de Nemours Company gave results worthy of further investigation. The high-speed copper-plating process plates from a hot alkaline bath consisting of copper and sodium cyanides and sodium hydroxide. The work is placed in a rotating barrel, the speed of which is regulated to obtain the best burnishing action on the copper as the magnets tumble over each other.

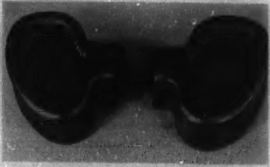

Figure 5. Left, magnet before plating; right, magnet after plating

With this process about 13.1 lb of copper can be deposited in 11 hours on 65 lb of magnets. This corresponds to an average deposition rate of 0.0017″ per hour.

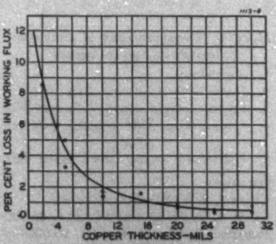

Figure 6. Effect of copper thickness on shielding of chrome-steel magnets

It was found in developing this process for the plating of magnets that the conductivity of the copper plating decreased very rapidly after the solution was used a few times. This condition was traced to an excessive concentration of sodium carbonates in the electrolyte. Excessive amounts of this compound also cause the deposit to be rough and pebbly. It was found necessary to periodically chill the solution and allow the carbonates to crystallize out.

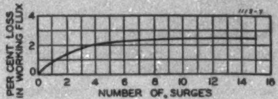

Figure 7. Effect of repeated 30x50 microsecond surges of 30,000 amperes on copper-plated chrome magnets

Figure 4 is an enlarged cross section of a plated magnet.

In order to obtain the maximum calibration adjustment on the assembled magnet, it is necessary to leave the upper pole tip unshielded. This is accomplished by placing a short length of rubber tubing over the upper pole tip before plating. The tubing is thick enough to completely fill the air gap of the magnet, thus reducing the amount of material to be removed in the final grinding. Figure 5 shows a magnet before and after copper plating.

Figure 8. A complete assembly of copper-plated magnets

Since the effectiveness of the shielding depends on the resistance of the plating, this property is used to control the quality of the product. As absolute values are not necessary, the procedure is to measure the total ohmic resistance of the magnet between points just back of the poles using a Kelvin double bridge. The addition of the copper plating reduces the total resistance from 340 microhms for the

THE current flowing in a short circuit in a simple a-c system can be expressed as a function of time in the form of three exponentially decaying components and a term which is substantially constant. These components are termed the subtransient, the transient, the d-c components, and the steady-state component. In actual systems all these terms are affected to some extent by the number of machines and the phase angles between them and also by their excitations. The phase relations between machines may change during the period of short circuit and thus introduce further complications. Automatic voltage regulators also introduce another factor which tends to increase the short-circuit current, since their action causes increase in machine excitation. Consequently, the accurate determination of short circuit current at any instant may be and usually is quite difficult.

Fortunately such rigorous calculations are not generally required to determine the proper application of interrupting devices and relay settings, for many other factors having greater proportional effect than the variations cited above contribute to the determination of the limits for rational choice of circuit breakers, expulsion protective gaps, fuses, etc. It is, therefore, perfectly proper and logical to make certain approximations in the calculation of short-circuit current to permit simple solutions of electrical systems for the purpose of applications of equipment. Such assumptions have been in general use for a considerable time and recognized by the electrical engineering profession.[1] An early approximation took the form of decrement curves which could be utilized if the reactances of the component branches of the system were known. As the knowledge of machine performance with the resolution of currents into the transient and subtransient components increased and the use of symmetrical components for unbalanced conditions became more generally known and accepted, the original decrement curves were revised[2] and placed on a more substantial basis. These curves, the present decrement curves, included provision for the determination of three-phase, line-to-line and line-to-ground short-circuit currents. At the same time other and more elaborate approximations[3,4] were offered which, while giving more accurate results, involved more extensive and complicated calculations.

The growth and interconnection of systems has resulted in a condition such that if the curves are applied according to the rules, values of impedance outside the range of the curves are often obtained, thus making the curves useless. Recourse was often made to certain expedients, such as the division of the system into several groups, each of which fed short-circuit currents into the short circuit independent of the others. These were so chosen that all the generators in a certain group were approximately the same electrical distance from the fault. In addition, frequent errors have occurred, even among those accustomed to the use of the curves, in confusing the kva of the arbitrarily chosen base on which calculations are made, with the kva of the system. The need undoubtedly exists for

---

steel alone to approximately 75 microhms for the combination.

Figure 6 shows the shielding effect of plated copper plotted against copper thickness. No appreciable increase in shielding is obtained after the coat is 0.020″ thick.

Figure 1, curve 5 shows the shielding effect of a 0.019″ thick plated copper shield using the surge values indicated on the figure.

Figure 7 shows the effect of repeated surges of the same magnitude on copper-plated magnets. Since the resistivity of the steel is fairly low (40.5 microhms/cm^3), an appreciable amount of self-shielding is obtained from the steel itself. This means that the demagnetizing effect of the first surge is limited to the outermost layer of magnet steel. After the surge has passed, the inner layers of steel remagnetize the outer layer, thereby weakening the whole magnet. Succeeding surges continue the process of demagnetizing fresh layers of steel until the demagnetized layer is so thick that the eddy currents induced in it are sufficient to prevent the further penetration of the transient flux. This is the same as saying that the demagnetization continues with succeeding surges until the intensity of the transient field minus the opposing intensity of the eddy current field equals the coercive intensity of the magnet material.

A complete copper-plated magnet assembly is shown on figure 8. This magnet is entirely interchangeable with unshielded magnets of similar design. Since the magnet material is the same as that used on unshielded magnets, the air gaps may be cleaned with magnetic cleaning tools without disturbing the calibration.

Summary

It has been shown that the problem of protecting permanent magnets from transient magnetic fields has been solved in a unique manner by the use of a new high-speed copper-plating process to apply a high conductivity copper shield over the conventional forged steel magnets.

Desirable features of this solution are complete interchangeability between unshielded and shielded magnets; forged steel material is used, which is fairly easy to obtain and on which unlimited operating experience is available.

the simplification, if possible, of the present methods of the calculation of system short-circuit currents. Fortunately, due to the increased use of higher speed circuit breakers and faster relaying, this need can be satisfied for an extremely large proportion of the present applications. It is the purpose of this paper to discuss this general problem and recommend simplified methods of calculation for different types of apparatus.

The modern trend of practice is to speed up materially the clearing of short circuits in order to reduce damage and maintain continuity of service. But, in general, the more quickly a short circuit is cleared, the greater is the current to be interrupted. Thus it is quite easy, by speeding up the relay system, to jeopardize the breakers by requiring them to interrupt more current than that for which they were initially chosen. Also quite often there is a tendency to save investment in breakers by the use of slow speed relays to take advantage of the decrease in short-circuit current due to its decrement with time, but even with slow speed relays, there is no guarantee that a short circuit will not change its character and initiate a high current flow in a breaker while it is opening. And there is always the danger of shortening the time setting of slow speed relays, which will tend to increase the interrupting duty on the breaker. Provision of breakers with interrupting capacity adequate for fast relaying is thus at least as essential a part of planning for the future as the usual allowance for increase in generating capacity.

This being the case, the problem of interrupting device application resolves itself into a study of what happens in a system during the first few cycles of short circuit. Even with fast relaying, modern high speed breakers for 60-cycle systems may be expected to part their contacts in times no shorter than given below:

8-cycle breakers—4 cycles (0.0666 second)
5-cycle breakers—3 cycles (0.05 second)
3-cycle breakers—2 cycles (0.033 second)
2-cycle breakers—1 cycle (0.0166 second)

In the above intervals of time, the effects of change in relative phase position and change in excitation from voltage regulators are negligible and permit eliminating their influence in the calculation of short-circuit values. Values so calculated will also be on the conservative side where some types of breakers in the above classes part their contacts in slightly longer times.

Figure 1 gives, in the full-line curves, the magnitude of the three-phase short-circuit current expressed in terms of rated current for various reactances as obtained from the present decrement curves, for the four instants specified; namely, 4, 3, 2, and 1 cycles which are related to the 8, 5, 3, and 2-cycle breakers as discussed above. The rated current and reactances are based on the system kva. Curves are given for both the total rms current and the a-c component only, the difference between the two being due to the d-c component. The larger the d-c time constant, the more closely is the total rms curve approached and the smaller the d-c time constant, the more closely is the a-c component curve approached. The time constant of the d-c component for which these curves were made is 0.15 second or 9 cycles. The d-c time constant may be expressed generally as equal to $\frac{1}{2\pi f}\cdot\frac{X}{R}$ in seconds, or $\frac{1}{2\pi}\cdot\frac{X}{R}$ in cycles, where X is the 60-cycle reactance and R the d-c resistance to the point of fault. Although ratios vary considerably, representative values of the ratio X/R for the major circuit elements for large equipment are given below.

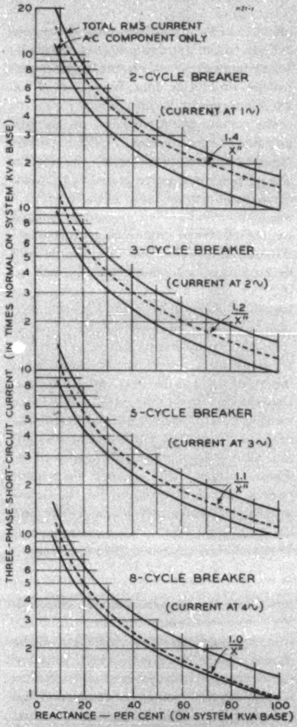

Figure 1. Comparison between decrement-curve calculations and calculations by the proposed method

		Corresponding Time Constant	
	X/R	In Seconds	In Cycles
Generators	80	0.21	13
Current-limiting reactors	50	0.13	8
Transformers	16	0.04	3
Transmission line	4	0.011	0.6
Cable	1.0	0.003	0.2

When any of these elements are connected in series relation the time constants of the combination become much smaller than that of a generator alone. Even a short length of transmission line has a marked effect upon the d-c component of current and a very appreciable effect upon the total short-circuit current. Table I shows the time constant of a particular combination for a fault at the generator, at the transformer terminals, and at two points out on an overhead line.

The Power Circuit Breaker Interrupting Problem

The reactances of figure 1 are based on the kva of the connected generator capacity. When the fault is near a generator the reactance is likely to be small and the d-c time constant large so that for small reactances the actual short-circuit current would approach the values given by the total current curves of figure 1. If, on the other hand, the fault is on the transmission line, the reactance is large and the time constant small. Thus, for large reactances the actual currents approach the values given by the a-c component only. The intermediate curves (dotted) of figure 1 for circuit breaker opening times of 4, 3, 2, and 1 cycles have been computed by the relation $1.0/X''$, $1.1/X''$, $1.2/X''$, and $1.4/X''$ respectively, in which X'' represents the system reactance to the points of fault, subtransient reactances being used for all generators. The factors in the numerators were arbitrarily chosen so that the curves lay between the curves for the total current and a-c component of current, and so the values were numbers that can be remembered easily.

In these curves the effect of the arc drop, which may be quite considerable in decreasing the d-c time constant, has been neglected. For a reactance of 30 per cent an arc drop of only 1.5 per cent in combination with one-half per cent resistance in the system is all that is required to reduce the d-c time constant from the nine cycles used in the present decrement curves to three cycles. On a 440-volt basis this is equivalent to but 6.6 volts, a value that is easily attainable. A reasonably conservative value of arc drop is about 20 volts per inch so that on a 13,800-volt circuit, 1.5 per cent drop requires only about six inches of arc length.

Having shown through the medium of the decrement curves that the relations for 4, 3, 2, and 1-cycle opening times apply quite well for simple systems, the justification has been established for applying the same relations to more complex systems. The use of these simple relations circumvents practically all the disadvantages of the decrement curves enumerated previously. With this method of calculating it is necessary only to obtain the equivalent reactance, expressed in any manner, regardless of the system, and apply the appropriate factor to the reciprocal of the reactance.

The foregoing simplified rules cover practically all applications. For the few remaining, it is sometimes desirable to know the short-circuit current for times longer than four cycles. For these special cases, the present decrement curves[2] or more elaborate methods may be utilized.[3,4,6,7] However, these methods are discouraged in favor of the rules proposed in this paper.

In most cases, faults occur at a point in the system for which a certain amount of other apparatus intervenes between the generators and the point of fault, in which case, the d-c component decays rapidly and the actual current approaches the a-c component. Even if the fault occurs on a generator bus, it is likely that other generators contribute to the short-circuit current through transformers, transmission lines, or cables. Therefore, the calculated values of current will be conservative for most cases.

In extreme cases where all the fault current is produced by large generators located at the point of fault, an accurate calculation with all assumptions on the safe side might show values as much as 20 per cent higher than the values given by this procedure. For the most conservative practice, therefore, when this condition is approached the results may be increased or other methods of calculation used.

In the curves of figure 1 adequate allowance has been made for non-synchronous load. For most central station applications, the additional contribution from synchronous motors will be negligible but where there is an appreciable contribution from them, they should be taken into account. In industrial applications, synchronous motor contribution may be of the same order of magnitude as that from generators and hence must be taken into account.

Synchronous motors are usually operated at about unity power factor; hence the voltage behind their subtransient and transient reactances is but little above terminal voltage. They tend to increase the power factor of the load; hence indirectly they reduce the internal voltage of the system generators. In general, they are much smaller units than generators; hence all of their time constants are faster and the decay of their short-circuit current is more rapid. For all of these reasons, it is justifiable to make somewhat less allowance for the short-circuit current of synchronous motors than for generators. Transient reactance may, therefore, be used in calculating their contribution.

The contribution of induction motors can always be safely neglected at times of two cycles or more.

The Momentary Problem

For many purposes, it is necessary to know the maximum possible rms current which can flow in the circuit. This is given by the current, including both a-c and d-c components, as calculated at one-half cycle. Allowing for overexcitation of generators on account of load, the rms value of current as calculated for zero time is about 1.8 times the value calculated by dividing leg voltage by subtransient reactance. As there will always be some decay even in the first half cycle, however, 1.6 times this value gives a safe figure.

In some instances, as when transmission line or cable reactance is an important factor in the limitation of current, the factor 1.6 may be higher than necessary.

In such applications, at 5,000 volts and below, the ratio of reactance to resistance is sufficiently low so that the d-c component decreases very greatly during the first half cycle. Thus within this voltage range, and except where the bulk of the power is supplied by generators at the point of fault, a standard factor of 1.4 may be used instead of 1.6. A standard factor is particularly desirable in consideration of the difficulties of obtaining actual resistance figures and the distribution of the d-c component among contributing short-circuit sources.[5]

Examples

All of the foregoing has been carefully checked by the calculation of specific examples. Figure 2 has been calculated for four representative simple cases as follows:

1. A representative turbine-generator with both transmission and fault at generator voltage.
2. A representative turbine-generator with a step-up transformer and both transmission and fault at 230 kv.
3. A representative hydro-electric generator with both transmission and fault at generator voltage.
4. A representative hydro-electric generator with a step-up transformer and both transmission and fault at 230 kv.

In each case the transmission line was assumed to have a length of one quarter mile per kilovolt and to have sufficient copper section to carry the entire generator output (either in one line or in several parallel lines) at a current density of 1 ampere per 1,000 circular mils. An arcing fault is assumed with an arc drop of 150 volts at generator voltage and of 2,000 volts at 230 kv.

The points corresponding to the coefficients 1, 1.1, 1.2, 1.4 and 1.6, at 4, 3, 2, 1, and $^1/_2$ cycles respectively are shown on figure 2, and it will be observed that they represent with reasonable accuracy the currents obtained at their respective times.

Figure 2 may be considered representative of the general case in which although some power may be generated near the point of fault, the major part of the short-circuit current comes from some distance away. Figure 3 has been calculated on a similar basis but without any transmission line between generator and fault point. Here it will be observed that the currents are somewhat higher, particularly for times from two to four cycles. It is for this reason that the recommendation is made that some additional allowance be made when the major part of the short-circuit current is obtained from large machines located at the point of fault.

Selection of Apparatus

It is suggested that the following procedure be followed in calculating short-circuit currents for use in applying various kinds of equipment.

CIRCUIT-BREAKER INTERRUPTING CAPACITY

While there is a wide variation in system conditions, the following calculation will usually give a conservative value of required interrupting capacity.

(1). Calculate the highest value of initial rms symmetrical current on the basis of no load, normal voltage, whether for a three-phase, double-line-to-ground, line-to-line, or single-line-to-ground fault, using subtransient reactances for all synchronous generators. Use transient reactance of synchronous motors when their short-circuit contribution must be considered.

(2). Multiply by the appropriate factor for 60-cycle systems from those given below:

8-cycle breakers	1.0
5-cycle breakers	1.1
3-cycle breakers	1.2
2-cycle breakers	1.4

(3). When the condition is approached of a short-circuit fed solely by large machines at the point of fault, these results may be increased up to 20%.

(4). Low voltage (600 volts or less) air circuit breakers are often instantaneous in operation and part contacts during the first half cycle. These breakers, however, are rated on the basis of average current in the three phases, and circuits on which they are installed rarely have X/R ratios exceeding ten. This corresponds to an average rms current during the first cycle equal to 1.23 times the symmetrical current. Breakers may therefore be applied on the basis of $1^{1}/_{4}$ times the three-phase initial symmetrical current using subtransient reactance and including both synchronous and induction motors.[5]

In order to co-ordinate this method of application of low voltage breakers with the conventional method used for other types of breakers, it is interesting to note that an average current for the three phases equal to $1^{1}/_{4}$ times the symmetrical current corresponds to a total rms current in the phase carrying the maximum unsymmetrical current equal to 1.4 times the initial symmetrical component.

In making the calculation for the equivalent system impedances, it should be remembered that at low voltages small impedance values become of importance and all elements of the circuit including current transformers, disconnects, switches, circuit breakers, bus runs, lead wires, et cetera should be taken into consideration.

MECHANICAL STRESSES AND MOMENTARY RATING OF CIRCUIT BREAKERS

The initial mechanical stresses due to the flow of electrical currents and the momentary rating of a circuit breaker are dependent on the maximum possible current which can flow at any time.

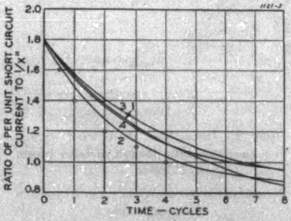

Figure 3. Three-phase short-circuit current from generators fully loaded at rated power factor

Arcing fault at generator or transformer terminal

1. Steam-turbine generator, 0.8 power factor without transformer
2. Steam-turbine generator, 0.8 power factor with transformer
3. Hydroelectric generator, 0.9 power factor without transformer
4. Hydroelectric generator, 0.9 power factor with transformer

Circles show points proposed for calculating duty of equipment

(1). Apart from cases covered by (2) below, the current to be used is 1.6 times the maximum value of rms symmetrical current using subtransient reactance values of both synchronous and induction machines.

(2). At 5,000 volts and below a factor of 1.4, instead of 1.6 should be used except on busses to which the major portion of total fault current is supplied either by directly connected synchronous machines or through reactors.

Directly connected synchronous machines are to be considered as those supplying fault current directly or through lines and transformers which reduce the contribution from those machines by less than 50%.

PROTECTOR TUBES

Inherent limitations of protector tubes require that a maximum and a minimum current rating be assigned to each tube for a given voltage. Because of the speed with which these devices become operative, it has been found possible to incorporate the variability of the d-c component into a rating which involves only the initial rms symmetrical a-c component of short-circuit current.[6]

Tubes should be applied so that the symmetrical short-circuit current at the point of installation of the tube, calculated on the basis of subtransient reactance for all combinations of connected synchronous machines and lines, should fall between the two limits assigned to the tube.

FUSES

Fuses are rated on total current and as the times involved are very short, their required interrupting capacity should be based on the total rms current at one-half cycle.

(1). In the general case, the current to be used is 1.6 times the maximum value of rms symmetrical current, using subtransient reactance for all machines, and including both synchronous and induction motor contributions.

(2). For fuses rated 15,000 V. or below with interrupting ratings not exceeding 3,000 amperes (except when applied on a generator bus) the resistance introduced by line and transformer is so great that the rms current of a maximum displaced wave in the first half cycle will not exceed 1.2 times the calculated symmetrical current, using subtransient reactance, and application on this basis may be considered safe.

PRELIMINARY RELAY SETTING

High speed current actuated relays can be given settings based on, first, the highest initial symmetrical current, using subtransient reactance at maximum system conditions, and second, on the lowest initial symmetrical current using subtransient reactance for minimum system conditions. Time over-current relays are usually set by use of similar values of symmetrical current using transient reactance values.

The settings of distance and pilot wire relays are assumed independent of the magnitude of short-circuit current but their accuracy may be impaired if the currents are outside of the range for which they were designed. This range is determined by the maximum initial symmetrical current for maximum system conditions and the minimum initial symmetrical current for minimum system conditions using sub-transient reactance values if the relays are high speed, or similar values of current calculated with transient reactance values if slower relays are used.

For bus differential relays it may be necessary to make an accurate calculation of both a-c and d-c components for assurance that operation will be satisfactory.

Conclusions

The precise determination of short-circuit currents involves a calculation so laborious as to be wholly impractical. Thus some approximation is required and a degree of judgment is required in the application of any method proposed.

The following rules are proposed for the various applications:

A. Circuit-Breaker Interrupting Capacity

Determine highest value of rms symmetrical current for any type of fault using subtransient reactance for synchronous generators and transient reactance for synchronous motors.

1. *General Case.* Multiply by the appropriate factor for 60-cycle systems from those given below:

8-cycle breakers	1.0
5-cycle breakers	1.1
3-cycle breakers	1.2
2-cycle breakers	1.4

2. *Short-Circuits Fed Predominantly by Large Machines at the Point of Fault.* Increase results of the general case up to 20%.

3. *Air Circuit Breakers Rated 600 Volts or Less.* Apply on basis of average rms current in all three phases, which may be taken as 1.25 times the rms symmetrical current.

B. Mechanical Stresses and Momentary Rating of Circuit Breakers

Determine highest value of rms symmetrical current for any type of fault using subtransient reactance for both synchronous and induction machines.

1. *General Case.* Multiply by 1.6.

2. *At 5,000 Volts and Below Unless Fault Current Is Fed Predominantly by Directly Connected Synchronous Machines or Through Reactors.* Multiply by 1.4.

C. Protector Tubes

1. *Maximum Rating.* Use the highest value of rms symmetrical current determined as in *B* with no multiplying factor.

2. *Minimum Rating.* Use the lowest value of rms symmetrical current determined as in *B* for minimum system conditions, with no multiplying factor.

D. Fuses

Determine highest value of rms symmetrical current as in *B*.

1. *General Case.* Multiply by 1.6.

2. *At 15,000 Volts or Below With Interrupting Ratings Not Exceeding 3,000 Amperes.* Multiply by 1.2.

E. Basis for Preliminary Relay Settings

1. *High Speed Current Actuated*

(*a*). Highest rms symmetrical current based on subtransient reactance at maximum system conditions.

(*b*). Lowest rms symmetrical current based on subtransient reactance for minimum system conditions.

2. *Time Overcurrent.* Make the same calculations as for high speed relays, but use transient reactance.

As compared with the latest decrement curves,[2] this method of calculation of short-circuit currents is somewhat simpler and should reduce considerably the possibilities of misapplication.

This method is in accordance with the present trend toward high speed relaying and eliminates the possibility of exceeding breaker interrupting capacities by modernizing the relay system after installation of the breakers.

It recognizes the acceleration of the decay of the d-c component of short-circuit current caused by the relatively high resistance of circuit elements other than the generator.

Table I. Effect of Location of Fault Upon D-C Time Constant

Location of Fault	Impedance to Point of Fault		$\frac{\text{Total X}}{\text{Total R}}$	Time Constant	
	X	R		In Cycles	In Secs
Generator terminals	20	0.25	$\frac{20}{0.25}$	13	0.21
High-voltage side of transformer	28	0.75	$\frac{28}{0.75}$	5.9	0.10
Inclusion of line having 5 per cent reactance	33	2.0	$\frac{33}{2.0}$	2.6	0.044
Inclusion of line having 10 per cent reactance	38	3.2	$\frac{38}{3.2}$	1.9	0.031

All impedance on same base as generator.

In view of these advantages it is believed that this method will prove more satisfactory in practice than the present standard.

Power-Circuit-Breaker Ratings

R. C. VAN SICKLE
MEMBER AIEE

CIRCUIT breaker application is being simplified. A subcommittee of the protective devices committee of the AIEE has studied methods of calculating short circuit currents and has prepared a report which presents a simplified procedure based on standardized contact parting times and typical current decrements.[1] To facilitate the use of this method, circuit breakers should have ratings which conform to the short circuit characteristics assumed in the calculations. At the present time, while the industry is preparing a revised list of short-time current ratings for circuit breakers, an opportunity exists to correlate the short circuit ratings so that a breaker selected for adequate interrupting current by the new method automatically has ratings adequate for the other short circuit currents.

The rating of a power circuit breaker as given by AIEE Standard 19-200 includes the following items:

(*a*). Rated voltage.
(*b*). Rated frequency.
(*c*). Rated continuous current.
(*d*). Rated short-time current.
(*e*). Rated making current.
(*f*). Rated interrupting current.

In addition definitions are given for the rated latching current and two short-time currents (the rated momentary current and the rated five second current).

The first three of these items are independent of each other. Breakers can be designed for any combination of rated voltage, rated frequency, and rated continuous current.

The rated making, momentary, five second, and interrupting currents are interdependent, being values of the maximum short circuit current permissible for the breaker.

The maximum short circuit current is determined by the impedance of the circuit and by the characteristics of the rotating machines supplying power to the short circuit. The initial current is composed of an a-c component determined by the subtransient reactance of the circuit, and a d-c component determined by the point on the wave at which the transient starts and by the circuit inductance and resistance. Both components are a maximum at the beginning and consequently the total rms current also is a maximum, figure 1.

This current during the first cycle is important as it is the maximum current to which the breaker will be subjected and corresponds to the rated momentary current and rated making current. In AIEE standards, "The rated momentary current is the maximum rms total current which the breaker shall be required to carry for any time however small up to one second.—" This current may be initiated either by a short circuiting of the system through some external means or by the breaker closing and completing a short circuit. Consequently, the first cycle current is also the current which the breaker must be capable of closing. By AIEE definition, "The rated making current of an oil circuit breaker is the maximum rms current including the d-c component against which the breaker must be capable of closing, without the welding of or undue damage to the breaker or contacts, with rated control voltage at the closing mechanism." Therefore, the rated momentary current and the rated making current should be at least equal to the maximum current which can be obtained during the first cycle.

Not all breakers are required to close completely and latch when making the rated current. For breakers having relatively low short circuit currents, the electromagnetic and other forces tending to oppose the closing of the circuit breaker may not impose much additional load on the closing mechanism and no difficulty may be encountered in the complete closing and latching of the breaker. Such breakers would have rated latching currents equal to rated making currents.

High interrupting capacity breakers for 15-kv service and below, have to make currents which may impose electromagnetic forces greatly in excess of the other forces opposing the closing, and may require a driving force considerably in excess of that needed for normal service. In this class of breakers, the closing and latching under short circuit conditions is a much more serious problem. The most advantageous position for carrying the current is with the contacts normally closed and the breaker latched, but with high speed tripping of the breaker it may be possible, without completely closing the breaker, to carry the current for the duration of the short circuit. However, the breaker contacts must be closed sufficiently to carry the short circuit current without undue burning or welding until such time as the short circuit is cleared elsewhere or the breaker tripped. In such cases the breaker will perform satisfactorily without latching and a rated latching current equal to the rated making current is not essential. Consequently, the rated latching current has no definite relation to the maximum short circuit current or to the rated interrupting current.

The sustained short circuit current must be carried by a breaker if it is not tripped. From its initial value, the current will decrease with the decreasing d-c and a-c components. The d-c component decreases approximately as a logarithmic function. The amount that the a-c component decreases will depend upon the effect of the short circuit on the generators. This effect is small if the generators do not form the principal limiting impedance and the a-c component may be sustained throughout the duration of the short circuit. Consequently, the maximum current which the breaker will be expected to carry for more than a few cycles while the d-c component is dying out, is the initial value of the a-c component. This value of the current corresponds to the 5 second rating of the breaker. By AIEE definition, "The rated 5 second current is the rms total current including the d-c component which the breaker shall be required to carry for 5 seconds." With increasing speed of breaker tripping this item is losing its significance.

Between the initial and the sustained currents is a current which the breaker must be able to interrupt. It is of great importance as it corresponds to the rated interrupting current which, by AIEE definition, "is the highest rms current at a specified operating voltage which the breaker shall be required to interrupt under the operating duty specified, and with a normal frequency recovery voltage equal to the specified operating voltage. The current shall be the rms value including the d-c component at the instant of contact separation as determined from the envelope of the current wave." The time at which the contacts separate and at which this current is measured depends upon the speed with which the breaker is tripped. It may be in the first cycle in the case of extremely high speed breakers, but is

generally somewhat later in the short circuit. The interrupting current is between the initial and the sustained values of the current.

The basic rating of a circuit breaker is its interrupting capacity at rated voltage. The interrupting capacity determines the strength of the parts which must carry the short circuit and withstand the forces incident to the interruption of the current. The voltage determines the clearances required for insulation. The normal rated current is a less important factor in determining the size of the breaker, although it does determine to a large extent the cross section of the conducting path, the size of the conductors through the bushings, and the size of the contacts within the breaker. Therefore, the rated interrupting current at rated voltage is the basic rating, and establishes the principal dimensions of a group or class of breakers. Various modifications of this basic design are made to take care of variations in the normal current carrying capacity. For example—a breaker may be developed and tested for an interrupting ability of 500,000 kva at 15 kv and minor modifications will give the various rated normal currents.

Circuit breakers are frequently used at service voltages less than their rated voltage. At these lower voltages, the difficulty of interrupting a given current is less and higher rated interrupting currents can be assigned. Constant kva, or a rated interrupting current varying inversely with service voltage, is customarily assumed. The wider the range of service voltages at which constant kva is maintained, the greater the range of currents which must be interrupted by the breaker. For best designs which have as little compromise as possible, it is desirable to limit the interrupting current, and a limit is established which permits the use of the breaker at full kva down at least to the next lower standard voltage. This maximum permissible current is called the interrupting capacity current limitation and is about 1.5 times the rated interrupting current at rated voltage, but varies, specially for 15-kv breakers which cover a wider voltage range. This rating is one value of the highest short circuit current which the breaker can be required to pass.

The interdependent items of the circuit breaker rating, making current, momentary current, interrupting current, and five second current correspond to currents measured at various points on the short circuit transient current. If definite ratios exist among these values, the ratings of the circuit breaker should correspond to these ratios so that no one of the items becomes the limiting factor and so that if a breaker is selected for adequate interrupting capacity, it will automatically be able to make and to carry the currents associated with that interrupting capacity.

These requirements are related, but in the past variable times allowed for the tripping of the circuit breaker resulted in various durations of the length of the short circuit prior to the parting of the contacts and consequently a variation in the ratio between the initial current and the interrupting current. Consequently, it has not been possible to use definite ratios and any one of the ratings has been able to prevent the application of the breaker on a particular service.

Table 1. Favorable Relations of Interdependent Circuit-Breaker Ratings

Rating Item	Current		
	Measured After Start of Short Circuit at Time Interval of (Cycles)	Ratio of Rating Item to Interrupting Capacity Current Limitation	Ratio of Rating Item to Rated Interrupting Current (Approximate)*
8 Cycle breakers			
Rated making current	0.5	1.6	2.4
Rated momentary current	0.5	1.6	2.4
Rated interrupting current	4	0.67	1
Interrupting capacity current limitation	4	1	1.5
Rated five second current	60	1	1.5
5 Cycle breakers			
Rated making current	0.5	1.45	2.2
Rated momentary current	0.5	1.45	2.2
Rated interrupting current	3	0.67	1
Interrupting capacity current limitation	3	1	1.5
Rated five second current	60	0.9	1.35
3 Cycle breakers			
Rated making current	0.5	1.33	2.0
Rated momentary current	0.5	1.33	2.0
Rated interrupting current	2	0.67	1
Interrupting capacity current limitation	2	1	1.5
Rated five second current	60	0.83	1.25
2 Cycle breakers			
Rated making current	0.5	1.14	1.7
Rated momentary current	0.5	1.14	1.7
Rated interrupting current	1	0.67	1
Interrupting capacity current limitation	1	1	1.5
Rated five second current	60	0.72	1.08

* The ratio beween the rated interrupting current and the interrupting capacity current imitation is a variable depending on the range of service voltages at which full interrupting kva is available. The table uses the ratio 1.5 which is the most common value, but it must not be assumed that this ratio applies to all breakers. Individual cases have conditions which justify using either arger or smaller ratios.

In the report referred to previously on the new method of calculating the current, the variable of the time of parting contacts has been eliminated by the assumption of definite contact parting times dependent only on breaker speed; after 1, 2, 3, and 4 cycles for 2, 3, 5, and 8-cycle breakers respectively. Likewise, the probable ratio between the initial a-c component and the total rms current during the first cycle and at the end of each of these cycles has been established. This new method assumes that the maximum asymmetry which can occur will make the total rms value of the current, at the time of the maximum peak, 1.6 times the a-c component, and that at the end of the first and succeeding cycles, this multiplying factor becomes 1.4, 1.2, 1.1, and 1.0. Consequently, the ratio of the current during the first cycle to the interrupting current for breakers parting contacts after 1, 2, 3, and 4 cycles are (1.6/1.4=)1.14, 1.33, 1.45, and 1.6, respectively. These factors are, therefore, the ratio of the initial current to the interrupted current of 2, 3, 5, and 8-cycle breakers respectively. They represent the minimum ratios between rated momentary current and rated interrupting current which permit utilization of the full rated interrupting current.

The values assigned to the interdependent items of a circuit breaker rating should be based on the interrupting capacity as this is the most important item. The interrupting capacity current limitation is determined from it by the range of voltages at which the breaker is to be used. This value is one measurement of the heaviest short circuit current which will be passed through the breaker. From it, the rated making, momentary, and five second currents can be obtained by use of the suitable factors. Table I shows the relations between these interdependent items as derived from the data in the report on the calculation of the interrupting current.

When low voltage breakers are used at service voltages, much below rated voltages, the making current may be high and require a very powerful closing mechanism. When used near rated voltage, the breakers may require much less energy for closing the corresponding making current. Such breakers could be adjusted to the requirements of the service by limiting the power input to the closing mechanism to that required for a making current corresponding to the rated interrupting current at service voltage. The saving in energy and wear on the breaker may justify this change which amounts of imposing a special rated making current and a special interrupting capacity current limitation which are determined by the reduced closing ability.

With ratings assigned in accordance with short circuit characteristics, circuit

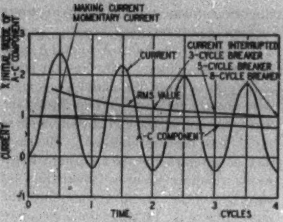

Figure 1. Short-circuit current

breaker application is simplified. Providing the current is calculated by the new method, the breaker can be selected on the basis of its rated interrupting capacity at the system voltage and the ratings of making current, momentary current, and five second current will automatically be adequate.

Since the rated making and momentary currents given in table I correspond to the interrupting capacity current limitations, they usually are higher than are required when a breaker is applied near rated voltage. When interrupting currents, calculated on the assumption of fast tripping, slightly exceed breaker ratings, a more detailed calculation using decrement curves might reveal that the making capacity is adequate and that the interrupting current is down to the breaker rating if a time delay of a few cycles is used.

If the advantages of the new method of short circuit calculation are demonstrated by experience and the method becomes used generally by the industry, another interesting possibility for the further simplification of breaker application should be considered. It gives exactly the same results as those obtained when breakers having ratings assigned in accordance with the assumed current transient are applied by the new method of calculation, but it eliminates from the calculation of the currents the factors dependent on breaker opening time and on special decrements for low voltage circuits.

Breakers could be applied on the basis of the initial a-c component of the short circuit current. The short circuit current calculations could be only the dividing of the voltage by the subtransient reactance to obtain the initial a-c component. The breaker ratings could consist of:

(*a*). Rated voltage.

(*b*). Rated frequency.

(*c*). Rated continuous current.

(*d*). Rated initial a-c component of short circuit current at rated voltage.

(*e*). Rated maximum initial a-c component of short circuit current at reduced voltage.

(*f*). Rated interrupting time.

(*g*). Rated latching current.

Breaker application could consist of selecting a breaker having these items at least as large as the system requirements. Circuit clearing time would depend on the speed of the breaker selected and the current calculation would be the same for 2-, 3-, 5-, and 8-cycle breakers.

Standardization rules could require of the manufacturer that his breakers be capable of closing carrying and interrupting currents having the rated a-c component at rated voltage and the a-c component current limitation at a corresponding lower voltage. Under these suggested rules, breakers would be capable of making a circuit having a total rms current equal to 1.6 times this maximum a-c component. They would be capable of carrying this momentary current. They would be capable of interrupting a total rms current equal to that specified for their contact parting time. They would be capable of carrying the a-c component for five seconds. Demonstrating or proving the performance of the circuit breakers would require these currents to have total rms values bearing the correct relations to the rated a-c component. On classes of breakers where special decrements are justified, for example 5 kv and below, the design of the breaker could be based on the special decrement characteristics and no change would be required in the current calculations. In other words, the requirements and results could be the same whether only the a-c component is specified and the testing requirements define the factors existing between the various currents, or whether as at present the various current values are calculated and checked for each application. Consequently, if the breakers were given rated initial a-c components of short circuit current at rated voltage and rated maximum a-c components at reduced voltage, the making, momentary, interrupting, and five second ratings could be eliminated.

In brief, the requirements would be determined by the initial a-c component of the short circuit current and a breaker selected which would have an adequate rated a-c component and which would be designed for making, carrying, and interrupting the corresponding total rms currents.

Conclusions

The ratings of a circuit breaker can be so correlated that full use can be made of the abilities of the breaker. With the new method of calculating the required interrupting capacity, and with breaker ratings assigned in accordance with the same current decrements, breaker application will be greatly simplified.

If, after trial, the new method of current calculation supplants the present method, a still further simplification in application can be obtained by rating a breaker on the initial value of the a-c component of the short circuit current which it can close, carry, and interrupt.

Lightning to the Empire State Building

K. B. McEACHRON
FELLOW AIEE

Synopsis: Lightning to the Empire State Building in New York City has been under investigation since 1935. Boys camera photographs of 62 strokes have been taken and 99 oscillograms. Twenty of these were taken simultaneously with photographs of the same stroke. Upward step leaders were discovered and continuing strokes were shown to be in the nature of a direct current arc. A brief résumé of the more important results up to the end of the 1937 season is given.

The paper is chiefly concerned with the oscillographic results of the 1938 and 1940 seasons. The low speed oscillograph in the Empire State Building recorded 17 of the 20 strokes to the building while the high speed oscillograph recorded 41 current peaks in 13 strokes.

1. Of 49 strokes recorded oscillographically during the years 1937–40, no stroke has been entirely positive although 41, or 84 per cent, were entirely negative. The first recorded current peak in stroke 13 was positive and had a crest current of 58,000 amperes.
2. Fifty per cent of the 49 strokes had charge of 25 coulombs or more, the maximum charge measured being 164 coulombs. These values are for the total stroke and not for current peaks.
3. Ninety-one per cent of all strokes recorded to the Empire State Building are classified as continuing, i.e. had a low current component.
4. Fifty per cent of the current peaks were found to have a crest current of 7,000 amp or more, while only 25 per cent of the 33 peaks measured in 11 strokes had a duration exceeding 40 microseconds.
5. The plotted data show that 50 per cent of the current peaks had a charge of 0.13 coulomb or more to half current value, although 5 per cent showed more than 1.5 coulombs.
6. A time of at least 1 microsecond is required to reach crest in 50 per cent of the current peaks, while 65 per cent reach the first crest in a time not greater than 1.5 microseconds—the time to crest of the present standard.
7. The results obtained show that rates of rise of the order of 10 to 20 kiloamperes per microsecond will be encountered quite frequently, and 30 to 40 kiloamperes per microsecond occasionally.
8. Errors as great as ±50 per cent may occur in connection with the highest rate of rise measurements; errors in connection with some of the other measurements may be as great as ±25 per cent, although most of the results will be more accurate than indicated by these figures.
9. It is pointed out that direct stroke data may be applied to transmission and distribution circuits if proper allowances are made for division of currents in the various paths including the effect of grounded neutral transformers. The current to be handled by lightning arresters will in general be much smaller than those measured in the direct stroke.

IN February 1939, the author published in the *Journal* of the Franklin Institute a paper[1] entitled "Lightning to the Empire State Building," and in May 1940 with K. G. Patrick, a book[2] titled "Playing With Lightning." These describe the Empire State investigation in some detail, while the instruments used have been described by Hagenguth,[3] Kettler,[4] and Flowers.[5] Therefore, only a brief mention will be made of the apparatus used, and a summary given of the important results obtained.

Equipment

At the Empire State Building are located two oscillographs—one arranged to record continuing currents up to one second duration, and the other to record the wave shape of individual current peaks. These have been called the low and high speed oscillographs respectively. At present both are of the hot cathode-ray type, although for several years the low speed oscillograph was of the electromagnetic type using a crater lamp for illumination. A schematic diagram of the operation of the high speed oscillograph is shown in figure 1. This equipment successfully[6] recorded in 1938 a multiple stroke consisting of (12) successive current peaks in 0.28 sec. Both of the oscillographs are connected to a non-linear shunt composed of thyrite and a linear shunt in parallel. With these shunts the low speed oscillograph records over a current range of 50 amps. to 24,000 amps., while the high speed range is 1,000 amps. to 200,000 amps.

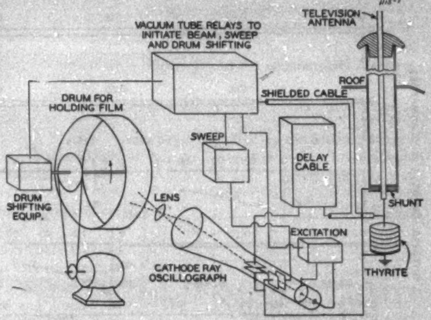

Figure 1. Schematic diagram of high-speed cathode-ray oscillograph equipment used for lightning investigation in the Empire State Building, New York City

Camera equipment is located at 500 Fifth Ave. a distance of 2,550 ft. to the top of the Empire State Building. Slow speed ($^1/_2$ rps) and (2 rps) Boys cameras are installed and also a high speed Boys camera normally having a film surface velocity of 124 ft. per sec. In addition, a moving film camera called a "multiple aperture camera" is used having four matched lenses so arranged that four images appear on the same moving photographic film along a horizontal axis. The lenses are provided with suitable filters and stop openings, so that a range of about one million to one may be obtained in exposure.

In addition to this equipment, another camera referred to as the "oblique camera" was installed on a building at the corner of 34th St. and 8th Ave. The purpose of this camera is to determine the shape of the stroke in a plane at right angles to that of the cameras at 500 Fifth Ave. so that a more accurate determination of the length of the stroke path might be made. This camera, controlled over a telephone circuit by the operator at 500 Fifth Ave., is not a Boys camera; its only purpose being to get the stroke shape, and no attempt is made to record detailed time effects.

A densitometer has been provided in the laboratory at Pittsfield for the study of changes in density found on the photographic records. All of the films used since the study began in 1935 have been provided with a sensitometer strip for calibration of the film against a known light source.

Means were set up in 1940 for the determination of visibility between 500 Fifth Ave. and the Empire State Building. This instrument was provided to make possible a fair determination of current from the Boys camera photographs, and studies are in progress to determine the change in current as one progresses up the

stroke—thus obtaining some data on the space charge around the stroke channel.

Brief Résumé of Results Previously Reported[1,2,6]

Some of the more important results obtained in this study, particularly with the camera equipment, are listed briefly below. Only oscillographic data are discussed in the present paper.

1. Discovery of the initial upward step leader mechanism from the Empire State Building.

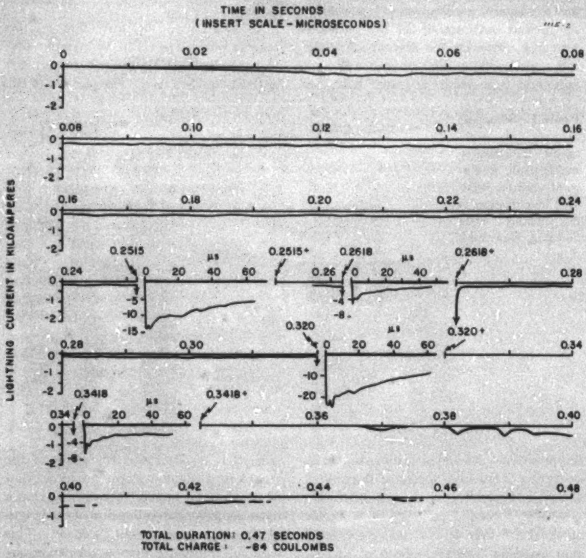

Figure 2. Composite replotted from low-speed and high-speed oscillograms showing our current peaks of stroke 3 to the Empire State Building

June 26, 1940 at 1:29.5 p.m.

2. Proof, both photographic and oscillographic of the existence of continuing current (substantially a direct current arc between line and ground).
3. Direct measure of charge in coulombs in lightning strokes, establishing a curve of frequency of occurrence for a given magnitude.
4. Oscillographic records show that out of 27 records all began with negative polarity, and 3 reversed polarity at end of the record, indicating that the base of the cloud is negative, and a positive region was reached in 3 cases only after a time interval.
5. Lack of so-called return stroke from clouds with upward initial leader mechanism, explained by lack of mobility of charges in clouds compared to the earth, which does produce a return stroke with downward initial leaders.
6. Strokes to ground, whether started by upward or downward initial leader, seem to have same mechanism for successive current peaks without reference to how initiated.
7. The configuration of electrodes probably determines the direction of propagation of initial leader.
8. Thunderless lightning results from relatively slow rates of current rise of upward leader strokes, without successive current peaks.
9. Measurement of leader and stroke propagation velocities and approximate determination of current required by upward step leader.
10. Identification of the upward streamer from earth when the downward initial leader approaches the earth.
11. Determination of wave shape of direct strokes—front, crest, and duration of current peaks of strokes having single peaks and as many as 12 successive current peaks (total of 4 strokes recorded).
12. Strokes to the ordinary countryside, in those cases where the photography was such that good measurements could be made, show the same general photographic characteristics as do those to the Empire State Building, once the stroke is established.

Additional Results

Considerable additional data obtained in 1940 are now available with respect to the wave shape of current peaks. Although many correlating oscillograms and photographs were obtained in previous years, during 1940 most of the strokes were not recorded photographically because they did not occur at night. It is believed, however, based on past experience that most of the strokes recorded were initiated by upward step leaders.

During the 1940 season the low speed oscillograph recorded 17 of the 20 strokes to the building, while the high speed oscillograph recorded 41 current peaks in 13 strokes. The correlation between the low and high speed oscillograms was excellent, there being a detailed record of nearly every current peak of any importance appearing on the low speed record. Such a record for stroke 3 (1940) is shown in figure 2, where the high speed and low speed records have been reproduced together.

Polarity

Of the 49 strokes recorded oscillographically during the years 1937–40, no stroke has been entirely positive although 41, or 84 per cent, were entirely negative. Of the eight strokes having some positive, one is known to have begun with a small positive current (about 200 amps), while four strokes began with negative current. With two other strokes, the current recorded initially appeared to be negative, but had too small a magnitude to be certain. As for the remaining stroke, the first current recorded was positive, although the oscillograph had initiated more than 0.025 sec. before indicating the presence of a current, whose magnitude and polarity is, however, unknown. This stroke (No. 13, 1940) is of considerable interest, as the first recorded current was a positive peak having a crest of 58,000 amps., which is nearly double the highest heretofore recorded oscillographically[6] to the building. This was followed by three negative current peaks, as shown in figure 3. The current peaks appear to be connected together by continuing current, mostly negative.

Stroke Charge

The stroke charge in the entire stroke including current peaks for 49 strokes is given in figure 4, and indicates that at least 50 per cent of strokes have a charge of 25 coulombs or more, although the average charge is 37 coulombs. The maximum measured in New York is 164 coulombs obtained in 1937, while in 1940 the maximum was 150. Three per cent of the total charge measured to date was positive.

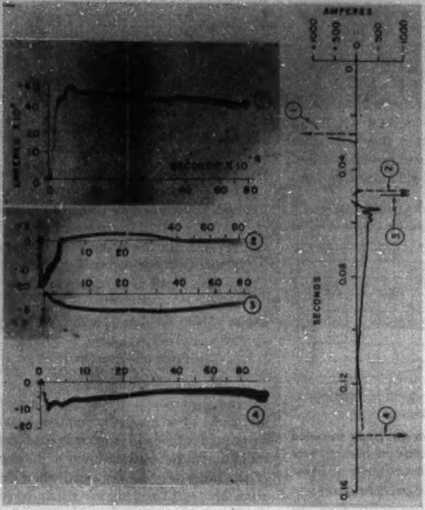

Figure 3. Low-speed and high-speed oscillograms showing four current peaks of stroke 13 to the Empire State Building

June 30, 1940 at 4:34 p.m. Time between peaks 0.021, 0.00092, and 0.087 second

Continuing Strokes

Of the 49 strokes recorded oscillographically, only seven did not show any signs of continuing current, and these due to lack of sensitivity might have recorded current under more favorable recording conditions. Of these oscillographic records 20 correlating Boys camera records were obtained—all but one showing the presence of continuing current. In addition to these photographic records 42 others were obtained—41 of which show the presence of continuing current. Thus 91 per cent of all strokes recorded in New York to the Empire State Building are classified as continuing.

It is of interest to record here that the results obtained thus far with the multiple aperture camera indicate that once a path is found between cloud and ground the current does not cease until the stroke is completed. The current merely increases and decreases in magnitude until the total stroke is completed.

1937, 1938, 1939, 1940

Based on 49 strokes

Coulombs in two-polarity strokes

	A	B	C	D	E	F	G	H
−	1.4	2.0	5.4	12	8.2	30	36	160
+	1.2	1.1	1.8	2.3	9.9	17	17	2.6

Other strokes negative charge only

Stroke Duration

The maximum stroke duration of 1.5 sec. reported in 1937 for a stroke to the building has not as yet been exceeded. Figure 5 shows that half of the 49 strokes recorded have a duration of at least 0.29 sec.

Current Peaks—Crest Current

The data given in figure 6 are plotted in terms of negative current peaks, since all the peaks recorded by the high speed oscillograph were negative but one, which is indicated. When comparing these data with those of other investigators, it is to be remembered that the magnetic link used in measuring currents through transmission towers[7] and distribution lightning arresters[8] indicate only the highest current peak occurring during the time the link is in service. In figure 6 each current peak in a stroke is plotted independently. It is not strange that Lewis and Foust give current values considerably higher than indicated in figure 6. The data given by McEachron and McMorris for distribution circuits are much lower in current magnitude, since the current was measured only at arrester locations, and in most cases is a measure of the traveling wave from some remote point. In many cases, too, the measured surge was the result of the release of a bound charge. The records do indicate arrester duty, but seldom the current magnitude in the stroke itself.

Duration

In terms of time to half value only 25 per cent of the 33 peaks measured in 11 strokes have a duration exceeding 40 microseconds, which is the present standard duration used in impulse testing in the United States. The maximum duration (figure 7) was 115 microseconds.

Charge

Since the tail of the current peak merges into the continuing current it is difficult to determine what is the current peak and what is continuing current. Therefore, when determining the charge in each current peak the area under the current-time oscillogram has been limited to the point where the current has decayed to half value. Figure 8 shows that 50 per cent of the current peaks measured have a charge of 0.13 coulomb or more, although only 5 per cent showed more than 1.5 coulombs.

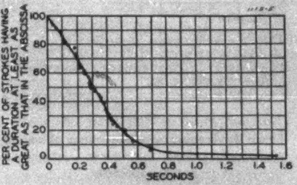

Figure 5. Stroke duration as a function of the frequency of occurrence

Values obtained from oscillographic records

Duration of multiple and continuing lightning strokes recorded by low-speed oscillographs

Empire State Building, New York City
1937, 1938, 1939, 1940

Based on 49 strokes

Since the cloud is not an infinite bus but has limited energy, one might expect that as the current increased the duration might decrease, but figure 9 indicates that the charge is increasing more rapidly than the current, which means of course that the duration is also increasing with the current. If the rate of propagation of the so-called return stroke is independent of the current in the stroke, and if the duration of the tail of the current peak is the time taken to reach the cloud, it would appear then that in general the longer stroke path will contain the greater current. There is yet no real support for either of these assumptions, nor is there any direct measure of the length of the stroke path compared to its current. Furthermore, large and small current peaks are recorded in the same stroke, apparently indicating the presence of other factors beside the length of stroke which may influence the amount of current. While ground resistance may have considerable influence on the amount of current, yet it must be remembered that all of the current peaks recorded in figures 6 or 9, occurred to a structure whose ground resistance was presumably quite constant—certainly it did not change during a stroke.

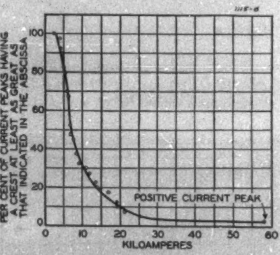

Figure 6. Frequency of occurrence of current peaks of various magnitudes determined oscillographically

Amplitude of current peaks recorded by high-speed cathode-ray oscillograph

Empire State Building, New York City

Based on 13 strokes

Wave Front

The time to the first crest is given in figure 10. These results show that a time of at least one microsecond is required to reach crest in 50 per cent of the peaks. Sixty-five per cent of the current peaks reach the first crest in a time of not more than 1.5 microseconds, the present standard time. It was of interest to plot the time to first crest against the crest value of current, but no trend could be found, except that higher currents usually required longer times to reach crest, but longer times did not necessarily mean a higher current peak.

Rate of Rise

The effective rate of rise in kiloamperes per microsecond, measured through the 10 and 90 per cent points is shown in figure 11. In considering these results it is well to bear in mind the difficulties encountered in recording and measuring accurately when the front becomes almost perpendicular to the time axis. It is clear that as the rate of rise increases the possibility of error increases, and therefore the highest values in figure 11 are to be taken with caution, since an error of the order of ±50 per cent may be present.

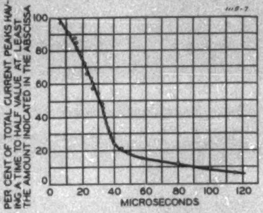

Figure 7. Duration of current peaks measured to half value as a function of frequency of occurrence

Based on 33 oscillographic records

Duration of current peaks recorded by high-speed cathode-ray oscillograph

Empire State Building, New York City 1938 and 1939

Based on 11 strokes

These results do indicate that rates of current rise of the order of 10 to 20 kiloamperes per microsecond will be encountered quite frequently in the stroke, and values as high as 30 to 40 kiloamperes occasionally. These values are to be compared with those of Norinder,[9] which are of the same general order of magnitude although obtained in Sweden by quite a different method.

Accuracy of Measurement

Measurement of the crest of the average current peak (9,000 amp.) is subject to an error of ±20 per cent. The major factors contributing to this error are difficulty in establishing a zero line, uncertainties in the measurement of deflections and in the value used for the oscillograph calibration including the lightning shunt. For smaller deflections, the error tends to be greater and may be less for the larger deflections.

Rate of rise measurements are subject to error in measurement of both current and time. For a crest current of 9,000 amps. and a time of one microsecond, error in the rate of rise measurement may be of the order of ±25 per cent, while for steep fronts (0.1 ms) the error may be as great as ±50 per cent.

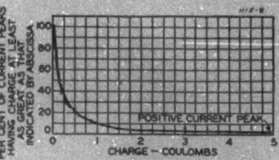

Figure 8. Charge of current peaks as a function of frequency of occurrence

Coulomb values based on time to half value of crest current

Charge in current peaks recorded by high-speed cathode-ray oscillograph

Charge passed until current decays to one-half of crest

Empire State Building, New York City 1938 and 1940

Based on 13 strokes

Measurements of charge are also subject to a possible error of ±25 per cent.

The low speed oscillograms are also subject to a possible ±20 per cent error in current magnitude; while currents smaller than 50 amps. are detectable, the accuracy is very poor, since the trace is often about 150 amps. in width.

It is believed, however, with the exception of the measurements depending upon fractional parts of microseconds, that the average accuracy is good for this type of measurement.

Discussion

Most of the oscillograms of current peaks show evidence of some oscillation near the crest (figures 2 and 3), having a magnitude of from 5 to 20 per cent and a period of about 2.5 microseconds. Since the building is 1,275 ft. high, perhaps this effect is the result of reflection phenomena at or near the base of the building. Of course the size of the building increases near the earth, which confuses the picture somewhat.

In applying these results to the case of lightning striking a transmission or distribution circuit, several assumptions must be made. It seems reasonable to assume that the sum of the currents flowing away from the point of contact with the lightning stroke will equal the current of the stroke, in view of what is now known of the mechanism of the stroke. Thus, if a line is struck at any point except close to

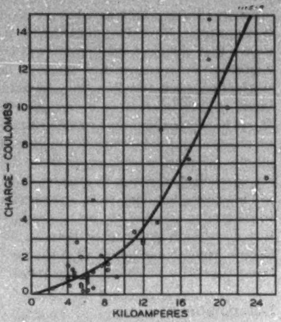

Figure 9. Effect of variation in crest current on the charge contained in each current peak

Relation between charge and crest current of negative current peaks

Charge passed until current decays to one-half of crest

Based on 13 strokes

Charge of only positive peak recorded was 4.9 coulombs with crest of 58,000 amperes

its end, the current in the stroke will divide equally and will have half of the magnitude of the original measured stroke current. The time to crest and half value will be the same as measured in the stroke itself, thus the rate of rise in terms of amperes per microsecond would be reduced to half that found in this investigation of strokes to a well grounded steel structure.

Current waves traveling away from the point struck are associated with a traveling wave of potential equal to the surge impedance multiplied by the current. Thus stroke 13, figure 3, having a crest current of 58,000 amps., the highest yet measured oscillographically, would have a traveling wave current of 29,000 amps. This corresponds to a traveling wave potential of 14,500,000 volts (using a surge impedance of 500 Ω) which would flashover any insulation now in use, either wood or porcelain. If, however, the stroke made contact with an overhead ground wire at a tower having a ground resistance of 10 ohms, the potential at the tower top would be only 580,000 volts, neglecting the current flowing away from the stricken point which would be only a little over 2,000 amps. until reflections from adjacent towers returned to increase the current.

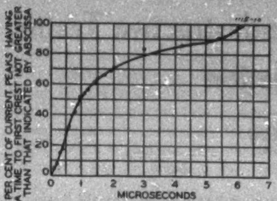

Figure 10. Time to first crest of current peaks as a function of frequency of occurrence

Recorded by high-speed cathode-ray oscillograph

Empire State Building, New York City 1938 and 1940

Based on 13 strokes

Thus the data obtained may be applied to transmission line conditions with reasonable accuracy. If the stroke is considered to have struck a considerable distance away from the ends of the line, then the traveling waves will contain a current half that shown in figure 6 and also a coulomb value of half that given in figure 8. If the stroke is at or very near the end of the line (within a few hundred feet) the traveling wave currents and corresponding voltages will be as originally given.

The wave shapes to reach apparatus will depend upon the point struck with reference to the apparatus, the insulation levels, surge impedance, coupling, and other factors. If overhead ground wires are used and the stroke does not initially make contact with the line conductors, the disturbance will be essentially local, if tower footing resistance is low enough and the line insulation high enough.

The total stroke consists not only of current peaks but also of long time low values of continuing current.

In the case of the transmission line, if the ground wire is struck these continuing currents find their way directly to ground. If the current peak was not of sufficient magnitude to cause flashover, the continuing current will not be of any importance, except for some burning of the ground wire which may result since this current is of the nature of a direct current arc.

If a continuing stroke causes an insulator flashover, the presence of the continuing current following arcover may interfere with the operation of the automatic reclosing equipment, if the latter is sufficiently rapid. Such continuing current in the conductors due to a stroke will be carried to ground through neutrals of transformers if grounded, while if the system neutral is isolated lightning arresters may be forced to carry such currents, which might possibly result in damage to the arrester, although in general the failures of arresters have been very small, indicating that currents of this character do not occur very frequently.

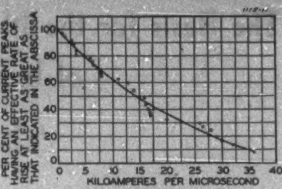

Figure 11. Effective rate of rise* of current peaks of lightning strokes as a function of frequency of occurrence

Recorded by high-speed cathode-ray oscillograph

* Slope of line through points on wave front at 10 per cent and 90 per cent of first crest

Empire State Building, New York City 1938 and 1940

Based on 11 strokes

In the case of distribution circuits, often several paths to ground exist over guy wires, through lightning arresters, and in the case of grounded neutrals continuing currents will find their way through many multiple paths to ground without undue duty on the lightning arresters. No doubt the continuing type of discharge is responsible for some of the fuses blown during lightning storms.

When using direct stroke data, such as given in this paper, to determine what may happen on either distribution or transmission circuits, proper consideration should be given to circuit conditions. Seldom, if ever, can direct stroke values be used directly.

It is also important to point out that there is good reason to believe that ground resistance will have an appreciable effect[1] on the current in a lightning stroke—the lower the resistance the higher the current, other factors being equal. The effect of ground resistance on wave fronts of direct strokes is not known, but one would expect that higher ground resistance would probably effect some increase in the duration of the stroke, although the effect of the cloud distribution of charge is probably controlling.[1]

Conclusion

For the first time, sufficient data relative to wave shapes of direct strokes are available to make possible the drawing of experience curves with respect to front, crest, and tail of current peaks. Similar data with reference to the total stroke are also available.

The Basis for the Nondestructive Testing of Insulation

R. F. FIELD
MEMBER AIEE

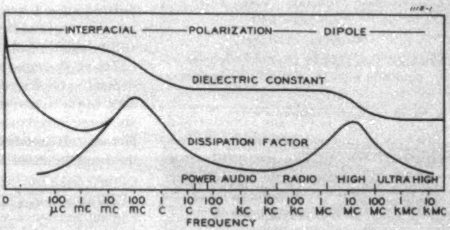
Introduction

DIELECTRIC strength is the property of insulation that is most important to the operating power companies. The factor of safety determined by the ratio of breakdown voltage to operating voltage must be maintained. Yet this breakdown voltage cannot be measured on a finished piece of insulation. Actual breakdown, except in the case of liquids, destroys the insulation. Overvoltage less than that required for breakdown has been found to injure the insulation and leave it with a reduced factor of safety. Non-destructive testing at overvoltage is feasible only if some electrical quantity, such as current, is measured and used as a sensitive indicator of incipient damage. The use of d-c overvoltage from a tube rectifier for cable testing is an example.

Non-destructive testing of insulation, as currently practiced, is the measurement of certain electrical characteristics of the insulation, such as capacitance, dissipation factor,* and leakage resistance, at a voltage not greater than the operating voltage. Ordinarily a relatively low voltage at the operating frequency is used, 100 volts to 10 kilovolts. Of these three characteristics, dissipation factor has come to be considered the most reliable indicator of the condition of insulation. The standard practice is to measure the dissipation factor of insulation at the operating frequency at stated intervals of time after installation. A progressive increase of dissipation factor with time is believed to indicate deterioration of the insulation. Certain limiting values are set depending on the type of insulation. When these limits are exceeded, the insulation is removed from service. Frequently, greater weight is placed upon continual change in the value of dissipation factor than upon its absolute magnitude.

Figure 1. Schematic diagram showing changes in dielectric constant and dissipation factor with frequency (after Murphy and Morgan)

The upper branch of the dissipation factor curve shows the effect of d-c conductivity



Heretofore the assumption has been made that, when insulation deteriorates, a correlation exists between the decrease in dielectric strength and changes in dissipation factor, because the use of nondestructive testing has resulted in a decrease of insulation failures. It is, however, a fact that the greatest success has been attained with the simpler types of bushings and insulators, only fair success with transformers, and little success with generators and cables. This is probably true because the changes in dielectric strength on the one hand and in the three measurable electrical quantities on the other are all effects for which deterioration is the cause. It is also unreasonable to expect that sufficient information will be contained in measurments taken at a single frequency to allow the different kinds of deterioration to be recognized. It will be shown that only by taking measurements over a wide frequency range can all the information obtainable from the electrical characteristics be secured.

These considerations make it desirable to determine whether or not a satisfactory correlation should exist between dielectric strength and one or all of the electrical quantities which can be measured.

Deterioration

The many causes of deterioration occuring in insulation may be grouped under four heads, chemical, mechanical, and electrical changes and the introduction of foreign material. The processing of many commercial dielectrics is incomplete. Either polymerization is not complete or the solvents are not completely volatilized. During the subsequent changes, voids may form throughout the body of the material. Voids are also formed in laminated materials under the vibrational and mechanical forces to which insulation is subjected in rotating machines and in transformers.

Foreign materials, mainly dirt and moisture, may adhere to the surface of insulation or may penetrate throughout the volume, if the body is porous. This is not usually an irreversible change. Cleaning and heating will usually restore the original properties, but, as long as the foreign material is present, dielectric strength may be impaired.

The existence of voids and the presence of foreign material offer the possibility of ionization, even at operating voltage. The surface of the voids will eventually carbonize and add a semi-conducting path. On the outer surface of an insulator this produces tracking. Permanent damage is done in either case.

Paper 41-118, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted December 5, 1940; made available for preprinting May 12, 1941.

Of these various kinds of deterioration the formation of voids and the absorption of moisture are most common.

Mechanism of Breakdown

Breakdown in solids has been studied extensively by von Hippel[1] and others. The application of a voltage produces a motion of free electrons and free ions toward the electrodes. If sufficiently long free paths exist, enough velocity is attained by these carriers of electricity to produce other ions by collision. As long as the motion of the carriers is limited, as by cleavage planes in crystals and by interfaces in mixtures, the insulation is stable. However, when the ionization becomes sufficiently intense, enough carriers are formed to blast an irregular path between the electrodes. This is breakdown.

Whatever increases the supply of free electrons and ions or lengthens their mean free paths lowers the breakdown voltage. This suggests that there may be a good correlation between dielectric strength and d-c conductivity.

Polarization

The values of dielectric constant and dissipation factor obtaining in insulation at any one frequency, or over a range of frequencies, are determined by the existing polarization. A value of dielectric constant greater than unity indicates polarization and an extra contribution to capacitance from polar groups. At optical frequencies a value of the refractive index greater than unity shows that some polarization exists. Any value of dielectric constant greater than the square of the refractive index indicates further polarization. A plot of dielectric constant against frequency has the general shape indicated in figure 1, which is after Murphy and Morgan.[2] The greatest value of dielectric constant occurs at zero frequency.

Two general types of polarization occur over the audio- and radio-frequency range, dipole and interfacial. The former was suggested by Debye and the latter by Maxwell, later amplified by Wagner. Dipole polarization is produced by polar molecules, in which the electrical centers of the positive and negative charges do not coincide. In an alternating electric field, such dipoles attempt to follow the direction of the field. At sufficiently low frequencies there is time enough during each half cycle for nearly all of the dipoles to place themselves in line with the field and that type of polarization is complete. The time required to carry the polarization to $1-1/e$ or 0.632 of completion is called the relaxation time. The corresponding frequency for which the polarization is complete usually appears in the megacycle range for the simpler polar molecules. For the more complex chain molecules, where dipoles occurring along the chain may produce a torsional vibration, this frequency may be found in the audio range.

The rotational motion of the dipoles is opposed by their own heat motion and the motion of the other molecules, with the result that a definite amount of energy is lost at each cycle. The power loss at any frequency is the product of the energy loss per cycle and the frequency. It decreases to zero at both zero and infinite frequencies and hence produces a maximum in dissipation factor at some intermediate frequency.

The d-c conductivity also contributes to the dissipation factor at very low frequencies and causes the numerical value of dissipation factor to become infinite rather than zero at zero frequency. This effect of d-c conductivity at very low frequencies is shown in figure 1, by the upper branch of the dissipation factor curve. For all ordinary dielectrics this contribution to dissipation factor is negligible at audio frequencies.

Interfacial polarization occurs at the interfaces of dissimilar dielectrics. These interfaces can occur as a few large surfaces between two materials or as innumerable small surfaces produced by finely divided particles. The free electrons and ions move throughout the volume of each dielectric and heap up at the interfaces. The charge accumulated at the interfaces during each half cycle contributes to the polarization in exactly the same way as does the lining up of the dipoles in dipole polarization. The resultant changes with frequency in dielectric constant and dissipation factor follow identical laws. In fact, it is not possible to distinguish the two types of polarization from the shapes of their frequency curves.

A condition necessary for the existence of interfacial polarization is an inequality in the product of dielectric constant and specific resistivity for the two dielectrics. This dependence of interfacial polarization on resistivity, and hence on free electrons and ions, suggests that there may be a good correlation between dielectric strength and the dissipation factor resulting from interfacial polarization.

Single Relaxation Time

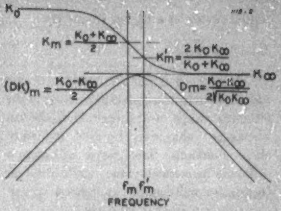

Figure 2. Change of dielectric constant, loss factor, and dissipation factor with frequency for a single-relaxation-time polarization

For a polarization having a single relaxation time the changes of the various electrical characteristics with frequency follow definite laws. The polarization is completely defined[3] by the high-frequency dielectric constant K_∞, the low-frequency dielectric constant K_0 resulting from complete polarization and the relaxation time T. The maximum value of loss factor* is

$$(DK)_m = \frac{K_0-K_\infty}{2} \tag{1}$$

and occurs at a frequency

$$f_m = \frac{1}{2\pi T} \tag{2}$$

which may be called the relaxation frequency. The curve of loss factor is symmetrical about the relaxation frequency and is expressed by

$$\frac{(DK)}{(DK)_m} = 2\frac{f/f_m}{1+f^2/f_m^2} \tag{3}$$

where both loss factor and frequency have been normalized with respect to their values at the relaxation frequency.

The curve of dielectric constant also has a kind of symmetry about the relaxation frequency and is expressed by

$$K = K_\infty + \frac{K_0-K_\infty}{1+f^2/f_m^2} \tag{4}$$

The value of dielectric constant at the relaxation frequency is the average value.

$$K_m = \frac{K_0+K_\infty}{2} \tag{5}$$

The shapes of these curves are shown in figure 2, where frequency and loss factor are plotted logarithmically while dielectric constant is plotted arithmetically. The curve of dissipation factor is also plotted logarithmically in figure 2. In its normalized form the expression for dissipation factor is identical with equation 3 for loss factor, with a maximum value

$$D_m' = \frac{K_0-K_\infty}{2\sqrt{K_0K_\infty}} \tag{6}$$

---

*Loss factor is the product of dissipation factor and dielectric constant.

which occurs at a higher frequency

$$f_m' = f_m\sqrt{K_0/K_\infty} \tag{7}$$

Whenever it is inconvenient to obtain values of dielectric constant because of the irregular shape of the dielectric, the capacitance values may be used instead in these equations. Loss factor will have a different numerical value, while dissipation factor will remain unchanged.

Multiple Relaxation Times

The curves obtained for the various dielectrics and for commercial insulation have very much broader maxima than the curve for a single relaxation time shown in figure 2. In addition, the value of maximum loss factor is much less than that calculated from equation 1. The explanation given by Wagner and amplified by Yager[4] is that there exists a group of relaxation times distributed according to some probability law.

The curves shown in figure 3 are given by Yager[5] for a paper base phenolic, curves 15*D* for a dry specimen and curves 15*H* for the same specimen conditioned at 60% relative humidity. The maximum in loss factor at a frequency of ten megacycles is produced by dipole polarization of the cellulose filler and the curve is much broader than that shown in figure 2. The slight rise appearing at audio frequencies in curve 15*D* and caused by interfacial polarization is greatly increased by the moisture added under the conditions of curve 15*H*. The relaxation frequency of this polarization is well below the audio-frequency range. This curve is so broad that loss factor is increased even at ten megacycles.

Circle Diagrams

Cole and Cole[6] have recently offered a simpler and more fruitful explanation for the broad maxima. The properties of a polarization having a single relaxation time are such that a plot of loss factor and dielectric constant, as shown in figure 4*a*, is a semicircle with its center on the dielectric constant axis and with intercepts on this axis equal to the zero and infinite frequency dielectric constants. It becomes apparent immediately that the maximum loss factor must be one-half the change in dielectric constant as stated in equation 1.

The important discovery of the Coles is that when loss factor is plotted against dielectric constant for various insulating materials a circular arc results whose center is depressed below the dielectric constant axis by an angle ϕ as shown in figure 4*b*. The ratio α of this angle to a right angle is taken as the fourth parameter in defining the polarization. It can be considered as a storage coefficient, which determines the ratio of the stored energy to the dissipated energy for whatever mechanism is assumed for the polarization. The data of figure 3 for a paper base phenolic are thus plotted in figure 5. The circular arc is well defined for the dry material and the divergence of the points at the low frequency end shows the existence of a second polarization. For the wet material the effect of the interfacial polarization is very marked but the data were not carried to low enough frequencies to define its circle. Values of the four parameters for the high frequency polarization are given in table I.

Table I. Paper-Base Phenolic

	K_∞	K_0-K_∞	f_m Mc	α
15*D*	3.76	1.08	14	0.52
15*H*	4.01	2.72	20	0.63

The addition of moisture, while slightly increasing the storage coefficient δ, has its greatest effect on the change in dielectric constant K_0-K_∞.

Effect of Temperature on Polarization

The effect of increasing temperature on both types of polarization is to decrease the forces opposing the motion of the carriers and thereby to raise the relaxation frequencies. This moves upward on the frequency scale all the curves of dielectric constant and loss factor without greatly changing their numerical values. At a given frequency dielectric constant always increases with temperature at the lower temperatures and consequently its temperature coefficient is positive. The magnitude of this coefficient is by no means constant but depends both upon the amount of polarization and on the ratio of the measuring frequency to the relaxation frequency. After the polarization is complete at a high temperature, dielectric constant frequently decreases and the coefficient becomes negative.

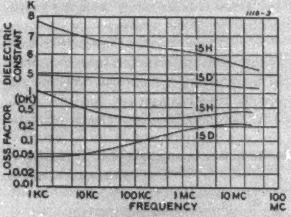

Figure 3. Change of dielectric constant and loss factor with frequency for a paper-base phenolic (after Yager)

15*D* dry, 15*H* conditioned at 60 per cent relative humidity

Loss factor and dissipation factor may increase or decrease with temperature depending on whether the measuring frequency is greater or less than the relaxation frequency. For most commercial insulation showing interfacial polarization the relaxation frequency is well below both audio and power frequencies, and the temperature coefficient is positive. It is always possible, however, for polarization from a single interface or from dipoles to occur at a higher frequency than the measuring frequency and make the temperature coefficient negative.

Effect of Voltage on Polarization

The effect on polarization of increasing voltage is to increase the amount of interfacial polarization because of the increase in the number of free electrons and ions. This will generally increase the value of maximum loss factor and decrease the d-c resistance.

Polarization in Commercial Insulation

Commercial insulation, as used in bushings and insulators, consists of a number of dielectrics in series and parallel. Interfacial polarization, with maximum dissipation factor occurring in the millicycle range,* is usual. Curves of capacitance and dissipation factor for a 25-kv compound-filled bushing are given in figure 6 for four different temperatures. These observations were taken on a Schering bridge operating at 100 volts. The shapes of the curves indicate the existence of both a high-frequency and a low-frequency polarization, but the frequency range is insufficient to allow the construction of circular arcs, even though the lowest frequency used was ten cycles.

The temperature coefficients are all positive and have the values given in table II.

The large variations in temperature coefficient indicate the difficulty of stating a single value applicable under all conditions.

---

*From 0.001 to 1 cycle per second. A frequency of one millicycle is 0.001 cycle per second.

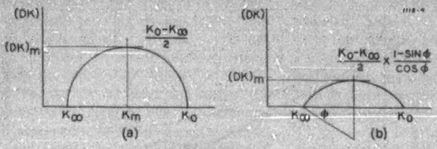

Figure 4. Circle diagrams (after Cole)

(*a*) Center of circle on dielectric constant axis

(*b*) Center of circular arc depressed by angle ϕ

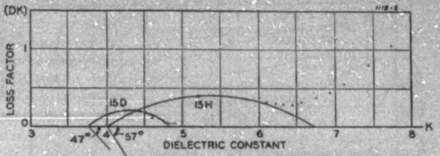

Figure 5. Circle diagrams for paper-base phenolic of figure 3

15*D* dry, 15*H* conditioned at 60 per cent relative humidity

Similar curves for a 66-kv multiple shell porcelain insulator are given in figure 7. Superposed on the low frequency polarization of the porcelain are the polarizations at the interfaces of the porcelain shells and the cement which holds the shells together. The changes in their relaxation frequencies with temperature amount to about 15% per degree centigrade. This is sufficient to cause the dissipation factor curves to cross each other and the capacitance curves to be anomalously spaced. The temperature coefficient of dissipation factor changes sign with both temperature and frequency and cannot be used for correcting to a standard temperature. The average temperature coefficient of capacitance at 60 cycles is 0.3% per degree centigrade.

Table II. Temperature Coefficients for 25-Kv Bushing

f Cycles	C % Per Deg C	D % Per Deg C
10,000	0.24	0.7
1,000	0.25	1.1
120	0.27	3.1
60	0.29	3.8
10	0.45	3.5

The change in the interfacial polarization of porcelain and cement as the moisture content of the cement is changed is startling. In figure 8 is shown the effect of allowing water to stand in contact with the cement for $5^1/_2$ hours. The relaxation frequency is raised to 800 cycles. Further soaking for 4 days raises this frequency to 13 kilocycles. Characteristic changes also occur in the capacitance of the insulator. The existence of such polarizations complicates the determination of the main low- and high-frequency polarizations, but affords added information concerning the structure of composite insulation.

Current-Time Curves

The interfacial polarization occurring in commercial insulation has been shown to be of such a nature that its relaxation frequency is well below the range of bridge measurements and in many instances is not greater than a few millicycles. Curves of charging current against time when a voltage is applied, or of discharge current when the voltage is removed, offer a feasible means of measurement. The existence of this charging current has been a great annoyance in the measurement of d-c resistance, and has led to such arbitrary rules as the specification that d-c resistance shall be calculated from the current flowing one minute after the application of the voltage. It is now obvious that resistance calculated in this manner is only an apparent resistance, which actually is a partial measure of the existing polarization. The complete curve contains the information needed to determine all the parameters which define the polarization. Whitehead and Banos[7] in 1932 analyzed charging current curves for paper taken by means of a cathode-ray oscilloscope and obtained values of dissipation factor which agreed within 2% with measurements taken on a 60-cycle Schering bridge. Murphy and Morgan[8] in 1939 placed this method of analysis on a better theoretical basis. They showed that charge and discharge currents differ by the d-c leakage current only when the polarization during charge has been carried to completion. It is necessary either to subtract the leakage current from the charging current before beginning the analysis or to carry the charging to a time which is long compared with the relaxation time before beginning the discharge. It is very difficult to estimate the correct value of leakage current, and the latter method is preferable in spite of the extra time involved.

The charging current at 500 volts for the 66-kv insulator is given in figure 9. After subtracting the leakage current of 0.62 $m\mu a$, the residual current was analyzed into the five exponentials shown, whose relaxation times vary from 0.4 to 63 seconds. The corresponding curves of dissipation factor are shown in figure 10. Their sum is the total dissipation factor

Figure 6. Effect of temperature on capacitance and dissipation factor of a 25-kv compound-filled bushing

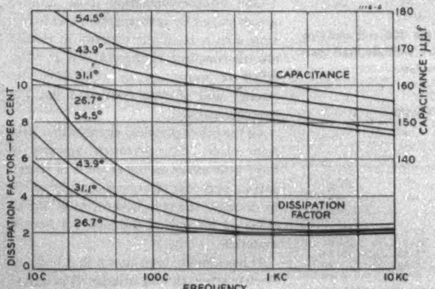

Figure 7. Effect of temperature on capacitance and dissipation factor of a 66-kv multiple-shell, pin-type, porcelain insulator

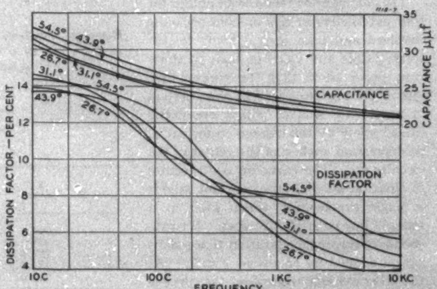

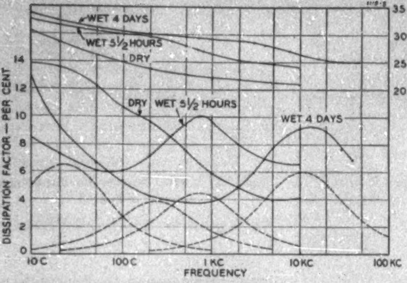

Figure 8. Effect of moisture absorption on capacitance and dissipation factor of a 66-kv multiple-shell porcelain insulator

The contributions to dissipation factor from the polarizations at the cement-porcelain interfaces are shown in dotted lines

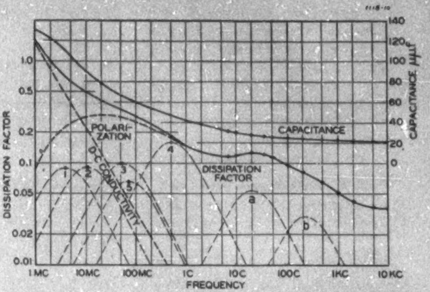

Figure 10. Capacitance and dissipation factor of a 66-kv multiple-shell porcelain insulator as calculated from the exponentials shown in figure 9

produced by the interfacial polarization. The contribution from the leakage current is then added. The corresponding values of capacitance are also given. The resulting circular arc is shown in figure 11. The falling-off of the values of loss factor at the low-frequency end is caused both by the difficulty of estimating the leakage current correctly and by the lack of long time data. The charging current should have been observed for a considerably longer time than 15 minutes. At the high-frequency end the points diverge because of the extra polarizations from the porcelain-cement interfaces. The four parameters derivable from the circular arc are given in the first row of table III.

Table III. 66-Kv Porcelain Insulator

Method	C_∞ μμf	$C_0 - C_\infty$ μμf	f_m Mc	α
Exponential	40.2	122.8	6	0.49
Graphical		115	5	0.4

The calculations required to obtain the four parameters in this manner are quite involved and take several hours to perform. Cole and Cole[9] in their most recent paper show that the current-time curves for any polarization have certain characteristic shapes, which are determined solely by the storage coefficient α, or depression angle φ of the center of the circular arc. The curve for α=0 (center of circle on the dielectric constant axis) is a single exponential, which plots as a straight line on arith-log paper. It corresponds to the single relaxation-time polarization defined by equations 1 to 7. At the other extreme when α=1 the curve is a 45° line when plotted on log-log paper. The family of curves are best plotted logarithmically on both axes. The observed current-time curve, plotted to the same scale, is matched to one of these curves and the values of storage coefficient α, relaxation time *T*, and current at that relaxation time noted. The residual current curve of figure 9 has been analyzed by this method with the results given in the second row of table III. The agreement between the two methods is reasonably good. It is quite necessary in this graphical analysis to use a discharge-current curve which covers at least three time-decades symmetrically disposed around the relaxation time.

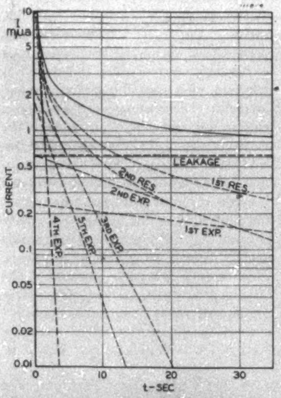

Figure 9. Analysis of the 500-volt charging current curve of a 66-kv multiple-shell porcelain insulator

5	289.0	8.82	2.55

Effect of Deterioration on the Polarization Parameters

The most common types of deterioration in insulation have been shown to be the absorption of moisture and the formation of voids. In a way they go together, because the existence of voids furnishes an additional porosity which can increase the moisture absorption. This appears to be particularly true of the pasted mica insulation used in large generators. The added moisture increases the dielectric-constant change $K_0 - K_\infty$ both on account of the high dielectric constant of water and also because of the added interfaces and free ions. The relaxation frequency f_m is usually increased. The effect on the storage coefficient α is not known.

The voids formed by chemical or mechanical means provide additional interfaces at which ionization can occur. Under intense ionization these surfaces are damaged by carbonization and oxidation with a resultant increase in the dielectric-constant change $K_0 - K_\infty$: The effect of ionization on relaxation frequency and storage coefficient has not been determined.

Of the other chemical changes that may take place, polymerization appears to have little effect on the amount of polarization, and loss of volatile matter seems to decrease the polarization, as would be expected because of the loss of a foreign material.

It has already been shown that both dielectric strength and interfacial polarization depend on the abundance of free electrons and ions. The changes in the three parameters K_0-K_∞, f_m, and α will not only measure the amount of the deterioration, but will indicate the type of deterioration as well and hence will suggest the probable decrease in dielectric strength. The success of such interpretation will depend greatly on the thoroughness with which interfacial polarization in typical insulating materials is studied by means of current-time curves.

An important by-product of these studies will be numerical values for the temperature and voltage coefficients of the three parameters. At the present time only their signs are known.[10] The dielectric-constant change K_0-K_∞ decreases slowly with temperature, but increases considerably with voltage. Relaxation frequency f_m increases rapidly with temperature, frequently at the rate of a decade in frequency for a rise of ten degrees centigrade. Storage coefficient α often decreases with temperature. The effect of voltage changes on these two parameters is not yet known. The importance of knowing the temperature coefficients is that it will then be possible to reduce data taken at widely differing temperatures to a standard temperature. Difficulties from rapidly varying coefficients such as were illustrated in figure 6 no longer occur for these polarization parameters.

Single-Frequency Measurements

Only when the kind of deterioration and the type of insulation is known will measurements of capacitance and dissipation factor at a single frequency afford a reliable measure of the amount of deterioration. The relaxation frequency is so low that it makes little difference whether an audio frequency or the power frequency is used. There is no virtue in using the operating frequency and there is considerable advantage in choosing some neighboring frequency, because it will then be much easier to eliminate the effect of the intense electric field at the operating frequency in which many measurements must be made.

Measurements spread throughout the audio-frequency range will add little to the information obtained from single frequency data, except as they may disclose unusual polarizations of the type shown in figures 5 and 6, and as they provide values of the infinite frequency capacitance and dielectric constant. These frequencies will be too far removed from the relaxation frequency to be of any help in constructing a circular arc and thereby determining the polarization parameters. For this same reason even wide changes in the applied voltage will have little effect on capacitance and dissipation factor, even though the changes in zero frequency capacitance C_0 and maximum dissipation factor D_m' are appreciable. Measurements made at the power frequency of 60 cycles on both new and deteriorated bushings at voltages from 50 volts to 10 kv bear out this conclusion.

Conclusions

It has been shown that a satisfactory correlation can exist between dielectric strength and low-frequency interfacial polarization in insulation, because of their mutual dependence on the abundance and disposition of free electrons and ions throughout the material. Any decrease in dielectric strength caused by deterioration can therefore be measured by the corresponding changes occurring in this polarization. The polarization is defined by certain parameters and a new method for their measurement has been outlined, involving the graphical analysis of current-time curves.

Radiobroadcasting in Canada

A. FRIGON
ASSOCIATE AIEE

Synopsis: The development of radio broadcasting in Canada has been very rapid and there are now 85 broadcast transmitters in daily operation. All broadcasting is under the control of the Canadian Broadcasting Corporation, an independent Government corporation, which in addition to its regulatory functions operates a coast to coast network connecting together, for a nationwide service, its own ten modern stations with almost half of the privately owned transmitters. It cannot therefore be said that radio in Canada is owned and operated by the Government as the CBC is independent and free to apply its revenues derived from licenses and commercial operation, in the best interests of its radio audience. The Canadian system is one of co-operation between a semipublic service and private ownership. Parliamentary enquiries have always found it the best suited to Canada's needs considering its vast area and relatively sparse population.

RADIO broadcasting in Canada began at about the end of the last War when an experimental station originated programs for a few hours a day. Following this the first network broadcast in Canada took place on Christmas Day, 1923, when an experimental station in Ottawa was connected to a station in Montreal. In 1926–27 an Eastern Canada network was organized extending from Moncton, N. B. to Toronto; then in 1928–29 our first coast to coast network was inaugurated. Shortly before this time however, on the occasion of the Diamond Jubilee of Confederation, July 1, 1927, Canada's capital city Ottawa was linked for the first time in a nation-wide broadcast using the combined facilities of the Telephone and Telegraph Companies in Canada.

Thus, in 1932, when the Canadian Radio Broadcasting Commission was created by Parliament, the principal wire companies in Canada were already providing facilities for network broadcast. In 1936, the Commission was superseded by the Canadian Broadcasting Corporation which took over the facilities and personnel of its predecessor.

The present system of radio broadcasting in Canada has, since 1928, been considered the best available by all parliamentary committees of enquiry on this subject. Moreover, the present corporation is different from the Commission, which controlled radio from 1933–36, but the principle of accommodating privately owned stations and public service systems has been recognized as the best for Canada for a number of years. The voting in the House of Parliament and of its special committees treating on radio has always been unanimous.

Of the 85 broadcasting stations at present operating on the standard frequency band in Canada, ten are owned and operated by the CBC; the balance are privately owned. Twenty-five of the latter and the ten CBC stations constitute our national network.

The CBC itself is an independent Government corporation, quite free to run its business as it may please, not using public money in any manner but operating with revenues provided by the receiver license fees contributed to the corporation by every owner of a receiving set; this is supplemented by revenues obtained from the commercial operation of the stations. Outside of permitting the corporation to pay for part of the network cost, the national network, commercially run by the corporation, does not bring any appreciable profit.

The CBC is a non-profit enterprise, operating within its own revenues and serving the interests of the public. There are no shares, there are no bonds. The Board of Governors is entrusted with the administration of the revenues placed at its disposal and is responsible for the honest and efficient conduct of the business to a Minister of the Crown. Any surplus in operation is considered as such and invested in the business. It is not distributed as profits and not returned to the public treasury.

On the other hand, privately owned stations operate under conditions similar to those existing in the United States. They conduct their business as they please, and their operating profit is theirs but, as in the United States, they must, pertaining to program only, submit to certain regulations which in Canada are formulated by the CBC.

The restrictions as to program, self-imposed in the case of CBC stations, are such that restraint of private stations is, in my belief, not serious. For instance, the CBC will not carry commercial spot announcements. It will not carry certain types of commercial programs and generally does not accept a great number of the local commercial programs. These restrictions and many others do not apply to privately owned stations.

To emphasize on this freedom of the commercial side of the business, I may state that there are three privately owned stations in Canada which are outlets of the American networks and there are four CBC stations also having direct network connections with American networks. These facts will immediately prove to you that broadcasting in Canada is neither owned nor operated by the Government.

Our dependence on American networks for a good many of our best programs presents some difficulties at times, but generally speaking, it is considered as a very welcome asset and a great means of fostering closer understanding between our two countries.

From the network operating point of view we have problems in Canada which do not exist in the United States. The CBC network, which is the longest east to west network in the world extending over three thousand air miles, covers five time zones instead of the four south of the border. This great distance separating the two extremes of the network and more particularly the great difference in local time renders the problem of co-ordinating the program service very difficult. In addition we have a bilingual population, as almost one third of all Canadians speak French. In the province of Quebec we have besides our basic trans-Canada network a Regional French network. The French speaking minorities located throughout the other eight provinces are however constantly clamoring for more French programs. This presents a problem requiring a good deal of attention. Of course our greatest difficulty in Canada is the same as that faced by our transportation companies and is due to the wide scattering of a relatively small population across an extremely large area. This means low revenue and yet high cost of service. In the United States there is twelve times the population in five-sixths of the area, while in England the British Broadcasting Corporation serves four times the population concentrated in but one sixty-fifth of the area. In normal times this must, at least from the engineering standpoint, be a broadcaster's paradise, where the whole network is hardly longer than some of our local loops and where lines are only a few

---

Paper 41-113, recommended by the AIEE committee on communication, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 10, 1941; made available for preprinting May 9, 1941.

A. Frigon is assistant general manager of the Canadian Broadcasting Corporation, Montreal, Quebec, Can.

hundred miles in length as compared to the five or six thousand miles some programs on this continent have to travel before reaching their destination.

The largest studios are located in Montreal and in Toronto where approximately 50% of our programs are produced. For exchange programs from or to American networks we have special switching facilities at Montreal and Toronto for the National Broadcasting Company Red and Blue networks, at Vancouver and Windsor exchanges with the Columbia Broadcasting System are handled, and again at Windsor for exchanges with the Mutual Broadcasting System and the Michigan Radio network. Broadcasts from the British Broadcasting Corporation in England are relayed to our network through our short-wave receiving station in Ottawa. At this station, we have directional aerials and diversity receivers constantly tuned to various points in Europe and South America. Before hostilities began important features or news gathered in this manner were broadcast over the network. From some of these sources activities are now necessarily curtailed. On the other hand, our relations with the British Broadcasting Corporation are even closer than ever. We have at the present time a number of our men in England working in conjunction with the British Broadcasting Corporation personnel.

One very interesting point is that the CBC is in the enviable position of being able to secure for its listeners, at any time, a greater variety of programs than are normally available to any other broadcasting system in the World. They are made up as follows: First it has access to the leading programs of all the principal networks in the United States. Second, broadcasts from Europe for the time being are limited to those from the British Broadcasting Corporation. Third, its own English network and fourth, its own French network.

Some special feature broadcasts have been of considerable credit to the CBC. An example of this was the Christmas Broadcast in 1935. During the two hour feature pick-ups were scheduled from some 35 different and in some cases almost inaccessible spots ranging from a point two miles under the Atlantic ocean to a golf course on an island in the Pacific. It was during this broadcast that eight choirs located at widely separated cities sang in perfect harmony with an orchestra at another point.

A more recent example involving still wider facilities was the Empire Day broadcast of May 24, 1939, during the visit of Their Majesties. The program which lasted an hour began with a rapid visit across Canada with Canadians speaking from Halifax, Montreal, Toronto, Winnipeg, Regina, Edmonton, and Vancouver then it carried the listener to Africa, Rhodesia, Australia, New Zealand, India, Jamaica, Newfoundland, Scotland, Northern Ireland, Wales, and England and then, to climax the broadcast, back to Winnipeg in Canada for the Empire Day message given by the King himself.

The Canadian contributions were brought together by land lines and those from other points of the Empire via short-wave radio relay lines. In Montreal all these elements were blended into a program which was relayed to 54 stations across Canada and 335 transmitters of the NBC, CBS, MBS, MRN in the United States and also to all parts of the British Empire by means of short-wave radio.

In all, we estimate that over 25,000 miles of telephone circuits and 100,000 miles of radio telephone links were used plus the services of some 2,000 technicians simultaneously engaged at the controls, constituting a program which was within the reach of millions of people.

Summing up, the CBC is mainly concerned with national and regional problems of broadcasting. This explains why it maintains a very elaborate network of broadcasting lines of a total length of over 7,000 miles reaching almost every broadcasting station in Canada. As a matter of fact, these lines are owned and operated for the CBC by our two main railway companies: the Canadian Pacific Railway and the Canadian National Railways. Under contract, the telegraph divisions of these two companies must maintain the wire line service between some 70 points across the country, the service being subject to certain specifications concerning the quality of transmission. This network permits the CBC to reach over 90% of the population of Canada within the primary coverage of some broadcasting station, that is within the 5 millivolts per meter contour of some station. If we consider that people living outside of these areas are for the most part isolated from industrial centers and can therefore obtain good reception from much lower field intensities, it may be said that the CBC network reaches practically all the population of Canada.

For commercial purposes, a group of stations has been organized as a network under the name of the National Network. This is composed of five regional networks which may be handled separately from a commercial point of view. Whenever some program of great national importance is handled by the CBC, for instance for all broadcasts of the Royal Visit or when our Prime Minister or your President has a message to send to the public, such broadcasts are offered to all stations in Canada. Those on the National Network carry the program, the others, while they are not obliged to, usually carry it of their own accord. This, I believe gives you a general outline of broadcasting in Canada.

It is difficult to give correct figures on privately owned stations as they are quite independent to run their show as they please and they are not required to submit a report on their financial operations except, of course, in so far as taxes or revenues are concerned, but files on these matters are not open to the public.

As I have said before, the CBC operates under a budget covering each fiscal year. Since its organization on the 1st of November 1936, the corporation has had a total operating surplus of $1,000,000—$600,000 of which has been re-invested in the corporation's plant. Our board is proud to have been able to operate a rather difficult business with a surplus each year. This is not always the case with organizations who may hope to obtain the help of the Government when they get into bad straights.

During less than five years since its inception, the CBC has built four 50-kw transmitters, one of 5 kw, a $7^1/_2$-kw shortwave transmitter, and new studios at two points. Besides this, a 5-kw transmitter was revamped as were two sets of studios. It also had the privilege of leasing from the Manitoba Telephone System the studios built by that organization in Winnipeg.

The Engineering Division is divided into five departments:

The Operation Department,
The Transmission & Development Department,
The Architectural Department,
The Design & Construction Department,
and the Purchasing & Stores Department.

Of a total staff of some 600 we have at present 185 employees in the main divisions of the technical service. Forty of these are graduate engineers and 100 are technicians and operators specialized in radio work.

Had it not been for the war we would probably have two important new buildings, one in Toronto and one in Montreal, to take care of our studio and office requirements at those points. The war has prevented heavy capital expenditures.

Although we ourselves fabricate a num-

Development in Lightning Protection of Stations

E. R. WHITEHEAD
MEMBER AIEE

Introduction

THE AIEE transformer sub-committee has recently sponsored a paper[1] on the protection of power transformers against lightning surges. The most effective method given combines overhead ground wires, line entrance gaps, and transformer mounted lightning arresters. Such a method does give a high degree of protection, but it is primarily applicable to high voltage, high capacity stations where the overhead ground wire system is justified for both line and station.

The conditions noted above are seldom fulfilled on subtransmission systems from 23 kv to 34.5 kv. Effective ground wires and low ground resistances are uneconomical, and the protection provided is usually a more or less modern arrester, not always located and grounded to the best advantage.

On the 23-kv subtransmission system of the Duquesne Light Company, the average transmission distance is approximately two miles. This means that most direct strokes will contact the line not more than one mile from some substation. Much of this transmission is now equipped with wood cross arm braces and guy insulators, and at some stations several spans adjacent thereto are carried on unguyed poles.

Under such conditions, it is possible for very high voltage waves to strike the station and result in arrester discharge currents having high rates of rise.

It is the purpose of this paper to outline briefly some of the field experience pointing to this factor as a cause of transformer and arrester failures, and to present a limited discussion of laboratory tests and calculations relating to a proposed method of achieving a high degree of protection for equipment so exposed.

Field Experience

After several years' experience with improved station insulation and modern types of carborundum block arresters,[2] it has become apparent that arrester failures are confined to a few exposed locations. Furthermore, most cases of insulation failure are associated with definite evidence of direct strokes to the line near the station.

In one station, no equipment failures have occurred, but arrester failures average one per year. In another station there have been no arrester failures, but transformer failures average one every two years. In still another case, the arrester suffered no damage but a transformer bushing flashed over. This particular bushing had an impulse strength over twice the arrester impedance voltage at 5,000 amperes on the standard AIEE test wave.

Such instances have emphasized the necessity of providing some sort of back-up device which would come into play under extreme conditions only, yet not affect service under the great number of minor surges.

In one station, six-inch rod gaps were installed in parallel with the arresters two years ago, yet another transformer failure occurred in 1940.

As a result of this experience, it was decided to make a series of tests in the laboratory in order to determine if some method could be found to afford protection under such conditions.

Performance of Arresters

In analyzing the performance of lightning arresters subjected to high rates of current rise, it becomes apparent that the so-called IR voltage depends both on the rate of current rise as well as on the maximum value of the current. It has been found that a fair approximation to the actual characteristic can be obtained by using an equivalent circuit composed of a constant voltage, a constant resistance, and a constant inductance in series.

Such representation is, of course, entirely empirical, and serves merely to permit approximate calculations. The method of determining the constants is shown in figure 1. The value of the arrester voltage drop at the time of crest current is plotted for two well-separated values of crest current, and the line joining these points extrapolated to current zero to determine the value of E_a. The slope of this line determines the value of R_a. The difference between the crest of the arrester voltage and the value at the instant of crest current is a measure of the fictitious inductive drop at this time. These values are not strictly constant, but

Paper 41-102, recommended by the AIEE committee on protective devices, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 8, 1941; made available for preprinting May 6, 1941.

---

ber of the minor parts of our equipment, we purchase the bulk of our plant from the usual equipment manufacturers. Our new 50-kw stations in Toronto and Montreal are Northern Electric transmitters. Those in Sackville and Watrous are RCA. We propose to co-operate with the Canadian Marconi in the operation of an F.M. transmitter on Mount-Royal, Montreal.

All our construction is designed and supervised by our own staff but actual building is assigned by tender to firms who are invited to bid.

Thus, it is seen that radio broadcasting in Canada is conducted under a dual system of individual privately owned stations and of a public service network operated by the CBC. This particular organization, besides having authority to regulate over program contents generally of private stations also owns and operates a number of its own stations and a network composed of both CBC and privately owned stations. Besides, the CBC acts as an agency in booking network programs on all network stations whether they are its own or privately owned. There is also a provision for the setting up of partial networks to meet special demands from sponsors or to take care of the overflow on the national or regional networks. This system has been in operation for more than five years and has proved to meet with the wishes of the very great majority of Canadians across the Country. The public service angle has proved extremely successful in certain instances of national importance and all indications are to the effect that present conditions will be maintained to the best satisfaction of the sponsors, artists, musicians, and the listening public.

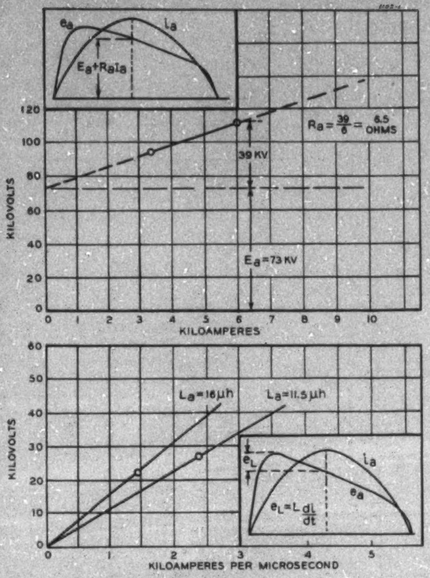

Figure 1. Method of determining constants for equivalent circuit of arrester

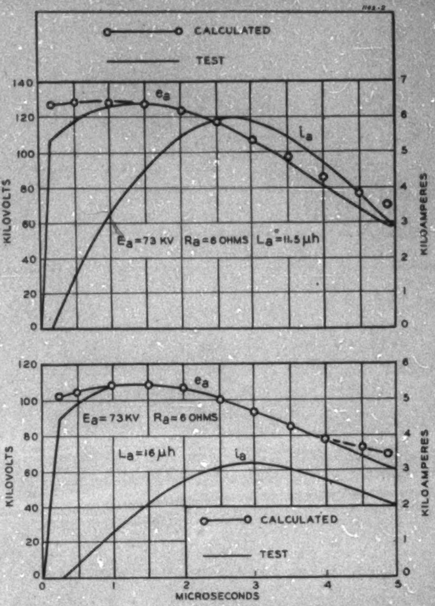

Figure 2. Comparison of test results and calculations from equivalent circuit

decrease with increasing discharge current. Values may be chosen for moderately high current and used with the knowledge that they will be conservative for extreme conditions. Figure 2 shows calculated and measured arrester voltages for the currents and arrester constants shown.

Transformer-Arrester Co-ordination

Because of the relative characteristics of gaps, transformers, and line type arresters, it is not possible to secure complete back-up protection for short times. This situation is illustrated in figure 3 where a modern transformer of the 23-kv class is compared with a modern arrester and a six-inch rod gap.

Gap-Reactor-Arrester Protection

Since the rate of rise characteristic of the arrester is simulated by an inductance, it seemed logical to add an external reactor which would increase the voltage at the gap location for high rates of current rise, and thereby at least partially offset the turn-up in the rod gap characteristic. This scheme is just the reverse of the old arrester-choke coil sequence in that the arrester is transformer-mounted and so limits the voltage at the vital point in the most effective way possible. In the old scheme, the arrester voltages for high rates of current rise were further aggravated by oscillations between arrester and transformer at the natural period of the choke inductance and effective transformer capacitance. In the new scheme, the basic protection is located at the transformer. The inductance and capacitance slope the wave front and lower the arrester breakdown, while the back-up gap is brought into action only when required to keep the arrester impedance voltage at a safe level.

Calculations for Theoretical Scheme

Figure 4 shows such a protection system. Through the substitution of the constant circuit elements to represent the arrester, it is possible to estimate the effect of any assumed terminal current. Although no "turn-up" is shown for the transformer strength, such an increase does exist and would actually provide a greater margin of safety than that indicated. The effect of this protection system at short times is roughly equivalent to the back-up protection of a 3.5-inch gap without the reactor.

Laboratory Tests

Impulse tests were made on the combination protective scheme in order to check the theory within the limitations of the laboratory equipment. Figure 5*a* shows the oscillogram of the voltage across the six-inch gap, while figure 5*b* shows the voltage across the arrester under the same conditions. Figure 5*c* shows the voltage across the arrester for a higher rate of rise of current, and without the reactor.

As a final test of the protection system, it was decided to make a complete set-up including a 100-kva, 3-phase, 22,000/460/230-volt transformer. The particular transformer chosen was an exact duplicate of those mentioned earlier as having flashed over or failed internally three times in six years. The surge generator was adjusted for maximum voltage and all series resistance was short-circuited. Under such conditions, the voltage, if unlimited by gap breakdown, would reach about 650 kv in something less than one-

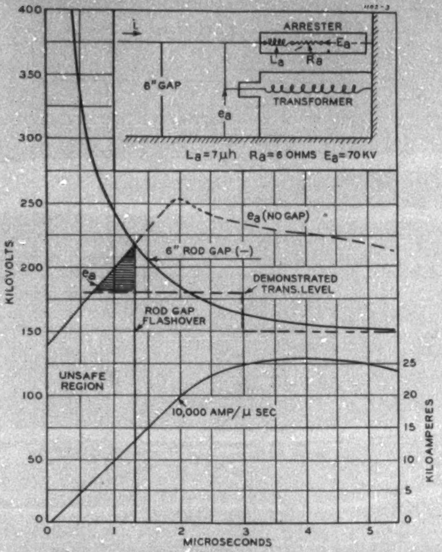

Figure 3. Co-ordination of gap-arrester-transformer combination

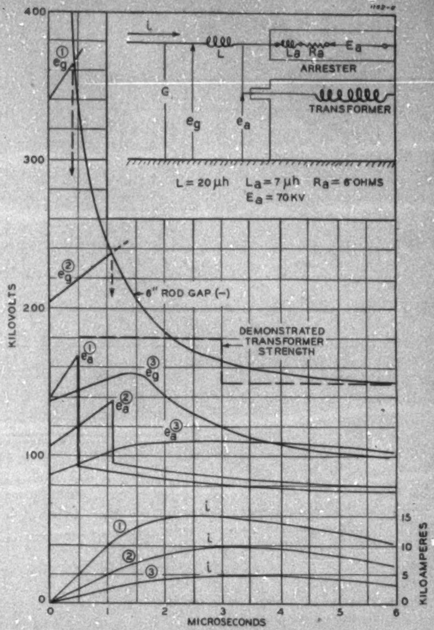

Figure 4. Calculated performance of gap-reactor-arrester protection scheme

half microsecond. Under these conditions, the generator was discharged into the system several times without damage to the transformer. A maximum voltage of 121 kv was recorded at the transformer bushing. Current measurements under such conditions were impossible, but it is estimated that the rate of current rise approximated 20 ka per microsecond.

Following this test, the transformer was subjected to both full wave and chopped wave tests slightly under the present AIEE standard values, and no evidence of insulation failure was detected.

Conclusion

It appears possible to employ a reactor or "choke coil" to compensate for the steep turn-up of rod gaps when the latter are used as back-up voltage limiting devices in conjunction with transformer-mounted lightning arresters. Moreover, such a combination gives promise of providing a high degree of protection to stations fed at subtransmission voltages over wood pole lines without overhead ground wires.

Current Rating and Life of Cold-Cathode Tubes

G. H. ROCKWOOD
MEMBER AIEE

Introduction

A COLD cathode tube is a gas discharge device capable of serving as a relay, a rectifier, or a voltage regulator.[1,2] It depends for its action upon the properties of gas discharges. The salient property employed is the fact that there is a difference between the breakdown voltage, or voltage necessary to initiate a discharge, and the sustaining voltage, or voltage drop across the tube when conducting. The principles involved are not new but a practical device capable of operating on voltages of 150 volts or less has awaited the relatively recent development of suitable cathode coating materials. The cathode surface employed at present consists of a coating of barium and strontium oxides applied to a nickel base. These oxides are partially broken down to barium and strontium metal during exhaust. During the operation of the tube the barium is continually removed from the cathode by sputtering and is replaced by further reduction of the oxide reservoir. The life of the tube is limited, therefore, by the amount of material present and by the rate of sputtering.

Because the cold cathode tube requires no cathode heating power it is well adapted to those applications in which the service is intermittent. The absence of a hot cathode implies no deterioration during idle periods and the ability of the tube to start instantly upon the application of an input signal. These properties have opened a wide field of use to the cold cathode tube and it is felt that this field may be widened if the tubes are so rated as to take cognizance of the fact that their life is determined by sputtering and the consequent exhaustion of the reservoir of cathode material. Other gas tubes, such as vapor rectifiers and thyratons, have been rated in terms of peak and average current. These ratings have been based on anode power dissipation and electron emission capability of the cathode surface. In the case of the cold cathode tubes it is desirable to have the rating bear a relationship to the rate of sputtering. For a tube of given manufacture, the rate of sputtering is determined solely by the current drawn. The general form of the life rating should be, therefore, a tabular relationship between the average life to be expected and the current. Several values of current and life are needed since the rate of sputtering is not proportional to the current.

If a cold cathode tube is operated until it fails in service certain changes may be observed visually. These are: first, a dark band on the tube walls in the vicinity of the cathode and, second, a change in color and surface appearance of the cathode. These observations may be accounted for by assuming that the cathode material is lost by either evaporation or sputtering. To test the idea of loss of material due to evaporation thermocouple measurements of the cathode were made. These measurements indicate that, in general, the cathode temperature is less than 250 C and invariably less than 375 C. These temperatures are so low as to make the theory of loss of material by evaporation untenable. For example, the cathode temperature at a current of 35 milliamperes was found to be 210 C and the average life 100 hours. Rudberg and Lumpert[3] have measured the vapor pressure of barium at low temperatures and give a formula by means of which their data may be extrapolated. From this knowledge of the vapor pressure of barium at 210 C and the total amount of barium present on the cathode the life may be calculated and it is found to be 45,000 hours compared to the 100 hours actually observed.

Microchemical examination of the tubes indicates that new tubes have considerable metallic barium on the surface of the cathode together with a much larger amount of barium in combination. Similar tests on tubes which have reached the end of their life indicate less metallic barium on the cathode and almost no barium in combination on the electrodes but the total barium which was present when the tube was made is to be found on other parts of the tube, notably the walls.

These facts lead to the conclusion that as the tube is operated barium is continually lost from the cathode surface by sputtering and is continually replaced from the reservoir of barium oxide provided in the cathode coating. When this reservoir is exhausted the tube reaches the end of its life.

Theory of Cathode Sputtering

Most of the literature on cathode sputtering relates to a discharge at relatively low pressures and with high voltage drops across the tube. The only comprehensive survey of sputtering in low voltage tubes is to be found in a paper by C. H. Townes.[3] A review of the conclusions reached by Townes is given below.

Townes divides the rate of sputtering into three factors: (1) the number of ions of a given energy striking the cathode, (2) the amount of material released by each ion, and (3) the fraction of material released from the cathode which diffuses away and ultimately reaches other surfaces in the tube.

There is good evidence that sputtering is due to ionic bombardment of the cathode and that the material sputtered leaves the cathode in all directions and in an uncharged atomic stage. In the low voltage cold cathode tube the cathode dark space, across which appears the cathode fall of potential has a thickness of several electron mean free paths. The mean free path for a positive ion being smaller than that for an electron, it is evident that very few, if any, positive ions reach the cathode with an energy corresponding to that of the cathode fall. The average energy of positive ions impinging on the cathode is found to be a little less than one electron volt. Not only the average energy is necessary but also the probability that an ion has any of the various possible energies. Appreciable variations in the total energy come principally from the variation in the energy acquired at the last free path of the ion. This follows from the fact that collisions between ions and gas atoms are collisions between particles of substantially equal mass so that on the average, an ion will lose half of its energy at each collision. On the average, therefore, the energy acquired by an ion in its last free path is double that which it had at the beginning of this last free path. The final expression for the distribution in energy of the positive ions striking the cathode is an exponential expression of the same form as that describing the distribution of molecular free paths in a gas. This is to

Paper 41-117, recommended by the AIEE joint subcommittee on electronics, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16-20, 1941. Manuscript submitted April 16, 1941; made available for preprinting May 12, 1941.

G. H. Rockwood is with the Bell Telephone Laboratories, Inc., New York, N. Y.

[1] For all numbered references, see list at end of paper.

be expected since, as pointed out above, the principal variation in the energy comes from that acquired in the last free path, or in other words depends upon the length of the last free path.

Of the mechanisms suggested for the release of material from the cathode under positive ion bombardment the one most successful in explaining the experimental results is the theory of local heating and resultant evaporation of von Hippel.[4] According to this theory the positive ion delivers its kinetic energy to a small number of atoms on the surface which are temporarily given large random velocities and evaporate from the surface just as they would evaporate if the entire cathode were heated so that they had the same thermal energy. The local hot spot of course, cools very rapidly by sharing its energy with the surrounding atoms. Townes has developed an expression for the number of atoms removed from the cathode by each ion impinging with a given energy. For a cathode material such that an atom must have an energy of four electron volts to escape from the surface his expression leads to the following:

Atoms Removed Per Ion Striking Cathode	Energy of Impinging Ions
2×10^{-8}	4 e.v.
0.2	6 e.v.
2	8 e.v.

This demonstrates the rapid variation in the number of atoms removed per impinging ion as the energy of the impinging ions is increased. The expression for the total number of atoms released from the cathode considering the distribution in energy of the positive ions reaching it is complicated and will not be given here.

Since the mean free path of the sputtered particles is much smaller than the distance between the cathode and surrounding surfaces a large fraction of the atoms which leave the cathode will diffuse back to the cathode surface so that they do not represent a net loss of cathode material. Townes shows that for a fixed rate of evaporation of atoms at the cathode the actual rate of loss of material from the cathode is inversely proportional to the gas pressure and depends as well on the distance to the nearest surfaces where deposition may take place. A large number of the evaporated atoms return to the cathode surface. The exact number lost will, of course, depend upon the tube geometry.

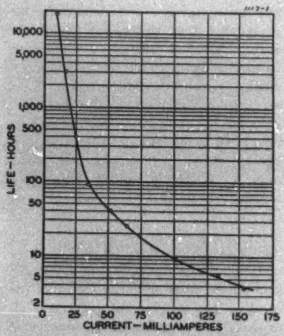

Figure 1. Life of the Western Electric 313C cold-cathode tube as a function of current

The complete expression for the sputtering rate is given by Townes as:

$$I = AF\frac{J}{p}e^{-\left[\frac{V_0}{c}\left(\frac{p^2}{Vi}\right)^{2/3}\right]} \qquad (1)$$

where

I is equal to the mass per second of sputtered material

p is the gas pressure in millimeters of mercury

V is the cathode fall in volts

i is the current density in amperes per square centimeter

V_0 is the energy in electron volts required to remove one atom from the cathode surface

c is a constant characteristic of the gas. For argon $c=20$, for neon $c=33$

J is equal to the total current

F is a function determined by the geometry of cathode and collecting surface. For plain parallel surfaces $F=1/d$ where d is the distance between the surfaces

A is another constant evaluated in terms of the properties of the cathode material in the gas

The constants in this equation may be approximately evaluated on theoretical grounds or they may be determined by experiment.

Experimental Results

A series of tubes have been operated at various currents to determine experimentally the relationship between current drawn and life. The cathodes of these tubes are coated to a nominal thickness of one-half milligram per square centimeter. This is an extremely thin coating and it is difficult to reproduce such coatings exactly from tube to tube. Considerable scattering in the test results must be expected therefore. The points on the curve of figure 1 each represent the average life of three tubes operated under the current conditions noted. The curve represents equation 1 with the constants so selected that it represents the best fit for the data. The agreement between the curve and the experimental data is seen to be quite satisfactory considering the scattering that must be expected in experiments of this type and suggests that the assumption at the outset that the life of the tubes was determined by the loss of cathode material due to sputtering is correct. This being so it seems reasonable to rate the tubes in such a manner as to reflect this fact.

The data presented in figure 1 relate to a Western Electric 313C vacuum tube and form the basis for the current ratings for this tube. The ratings employed are those currents which will give a life of 100, 1,000, and 10,000 hours. Because of the large scattering due to variations in coating thickness and gas pressure in individual tubes it is not expected that the life of a single tube can be predicted with an accuracy better than ±50%. In dealing with large numbers of tubes, however, the average life is predicted with a considerably better accuracy. It is practical, for instance, to use this curve in calculating the number of tube replacements required for a circuit which operates under given conditions.

Application of Current Ratings

Since the life of a cold cathode tube of given manufacture depends solely upon the current drawn a knowledge of the relationship between life and current drain is of vital importance to the circuit designer. In the use of cold cathode tubes it often happens that the duty cycle is so light that the life of the tube may be many times the life of the equipment in which it is used even though the tube, if operated continuously, might last but a few hours. If the circuit designer is furnished with the relationship between life and current drain and knows the duty cycle imposed on the tube he is in a position to determine the average life he may expect from the tube. With this knowledge it is often possible to apply small, inexpensive cold cathode tubes to circuits requiring considerable amounts of current for brief and infrequent intervals rather than to resort to larger tubes requiring hot cathodes and capable of supplying the current continuously. Likewise, it makes it possible for the designer to reach a reasonable compromise in decreasing the cost of associated equipment at the expense of increasing the current drain through the tube and therefore shortening the tube life.

If the current wave form through the tube is irregular the life may still be predicted by dividing the current wave into elements small enough so that the current in each element may be considered constant. Each of these currents may then be considered as lasting for a certain fraction of the cycle. For each of the current values obtained there is a life in hours which may be determined from figure 1. One then has a series of currents $i_1, i_2, \ldots i_n$ each lasting for a fraction $t_1, t_2, \ldots t_n$ of the entire cycle and a tube life corresponding to these currents of $l_1, l_2, \ldots l_n$. The fraction of life used up at each current per hour is, then t/l. The total fraction of life used up per hour is

$$\frac{t_1}{l_1}+\frac{t_2}{l_2}+\ldots\frac{t_n}{l_n}$$

and the socket life of the tube is

$$\text{socket life}=\frac{1}{\frac{t_1}{l_1}+\frac{t_2}{l_2}+\ldots\frac{t_n}{l_n}}$$

Conclusions

For tubes manufactured in any given manner the life will be determined solely by the current drawn. In view of the fact that the tubes do not deteriorate when they are not passing current it seems reasonable to operate them at very large currents if the duty cycle is sufficiently light. It is suggested, therefore, that the most useful type of rating for cold cathode tubes would be to state the current which will give a life of 100, 1,000, and 10,000 hours.

Dielectric Strength of Oil for High-Voltage Testing of Oil Circuit Breakers

H. J. LINGAL
MEMBER AIEE

W. F. SKEATS
MEMBER AIEE

H. D. BRALEY
ASSOCIATE AIEE

THE purpose of this paper is to report on work undertaken in response to a request, made to the Institute, to determine the minimum dielectric strength of oil for high potential testing of oil circuit breakers.

Many tests were made with 60-cycle and impulse voltages. The tests were made with a rod to plane gap, cone to disc gap, and on oil circuit breakers of commercial types and sizes. The results of these tests have been collected, analyzed, and are included in tabular form in the paper.

The impulse strength of oil circuit breakers was found to be practically unaffected by the 60-cycle breakdown strength of the oil within the range of 16 to 30 kv, as measured in a standard test cup.

The 60-cycle dielectric strength of oil circuit breakers is shown not to be changed in direct proportion to the differences in the dielectric strength of oil as measured in a test cup with 60-cycle voltage.

The effect of low dielectric strength oil on voltage breakdown is discussed and conclusions are drawn which show that it is desirable to test all oil circuit breakers with oil having dielectric strength of 22 kv or higher.

General

The general picture of oil breakdown for some years has involved the lining up of impurities over a period of time ranging from a small fraction of a second to several minutes, with breakdown taking place over the path so formed. From this standpoint it is to be anticipated that long gaps will be relatively less affected by the impurities in the oil than short gaps, and that breakdowns under impulse conditions, where time is not available for lining up of impurities would be less affected by impurities than breakdowns under a one minute test at operating frequency. This is supported by the fact that the impulse ratio of oil, as obtained by comparing Sorensen's[1] data on impulse tests with Miner's[2] data at 60 cycles is considerably greater than the impulse ratio for breakdowns over an air path. Hence, it would be expected that any equipment which will flash over in an air path in preference to an oil path at 60 cycles will have a good margin of safety for the oil under impulse conditions, and it is also to be expected that the dielectric strength of a completed assembly such as an oil circuit breaker would be much less affected by the presence of impurities, in the oil, particularly under impulse conditions, than would be

Table I. Rod-to-Plane Gap Impulse Tests

(See Figure 1)

Gap Spacing (Inches)	Oil	Highest Voltage Held Without Breakdown (Kv)	Lowest Voltage at Which Breakdown Occurred (Kv)
1	New	176	168
1	Old	165	166
2	New	200	186
2	Old	208	190

The tests were made with a $1^1/_2$–40 m.s. positive wave.

expected from values on oil dielectric strength obtained at 60 cycles in a standard test cup.

To verify this line of reasoning, impulse tests were made on sample gaps with good oil and oil deteriorated by the addition of carbon and moisture, 60-cycle tests were made under similar conditions on a gap much larger than that of the normal test cup, and finally tests were made on completed breakers of commercial design. As will be observed from the data set forth in the tables throughout the paper, these tests indicated in all cases less divergence of dielectric strength than shown in the standard test cup, and in the case of tests on the completed breakers negligible divergence.

Equipment Used

The data used by the authors in preparing this paper were obtained from tests made in the high voltage test laboratories of Westinghouse E.&M. Co. at East Pittsburgh, Pa., and General Electric Company at Schenectady, N. Y., and Philadelphia, Pa.

The oil circuit breakers on which the tests were made were complete commercial designs, sizes, and ratings.

The rod to plane gap was a special gap made by the laboratory and is shown in figure 1. When used for testing, the gap was immersed in a tank of oil.

The cone to disc gap on which tests were made is shown in figure 2.

The wet oil used in making the tests with the cone to disc gap was obtained by forming a saturated solution of water and oil at 80°C. and mixing in measured proportions with oil dried by bubbling dry air through it. The maximum water content was about 250 parts per million.

The used or carbonized oil was obtained from the dirty oil tanks in the laboratory and had previously been used for making oil circuit breaker tests until its dielectric strength had fallen to the point where it was considered necessary to recondition it before further use. In some cases the oil, having been taken from near the bottom of the tank, contained more than the usual amount of foreign material. When let stand without agitation for a short time, these materials tended to settle at the bottom of the tank. This accounts for the fact that in some cases the test value of the oil measured in a standard test cup with 60-cycle voltage varied from 4 to approximately 15 kv.

For the purpose of obtaining data on the dielectric strength of large gaps, using deteriorated oil, a 24-inch circuit breaker tank was filled with oil and a crosshead of corresponding size was supported in the tank in a position corresponding with that which it takes when the breaker is closed. An electrical connection was made to this crosshead through a high voltage bushing, and the tank itself was used as a ground terminal. See figure 3.

Impulse Tests on Rod-to-Plane Gap

Impulse tests were made on a rod to plane gap shown on figure 1. Tests were first made with new oil and then repeated with used oil. The new oil tested about 30 kv in a standard oil test cup. The

Table II. Cone-to-Disk Gap Impulse Tests (See Figure 2)

Ratio of Dielectric Strength Values

	60 Cycles		0.5 M.s.		1.5 M.s.		8 M.s.	
	Std. Gap	Cone Disk Gap	Cone Pos.	Cone Neg.	Cone Pos.	Cone Neg.	Cone Pos.	Cone Neg.

Carbonized oil	0.43	0.48	0.83	0.89	0.72	0.76	0.60	0.62
Wet oil	0.26	0.40	0.89	0.78	0.89	0.80	0.86	0.70

Table III. Low-Frequency Tests on Large Gaps (See Figure 3)

	Oil Dielectric Standard Test Cup Strength		60-Cycle Test With a Large Gap			
	Kv	Ratio	Voltage Held Quietly (Kv)	Noisy (Kv)	Breakdown Voltage (Kv)	Ratio* Max. Quiet
Good oil	30		130	135	150	
Carbonized oil	9	0.30	115	**	118	0.89
Wet oil	14	0.47	112	115	146	0.86

*The values in this column are the ratios of the maximum voltage held quietly by the deteriorated oil, to the maximum voltage held quietly in good oil.

**No noisy region found between voltage held quietly and breakdown.

used oil was taken from a breaker which had undergone severe interrupting duty. The breakdown of the used oil was erratic, varying from 5 to 15 kv.

In these tests, the gap was immersed in the tank filled first with new oil and then with used oil. The tests indicated that the impulse breakdown of the low test oil was as high as that of the new oil. Tests were made with the gap set at one inch and at two inches with results as given in table I.

The small difference in test voltage shown for the two gaps is possibly due to corona forming on the gap electrode at the higher voltage and reducing the voltage required to break down the longer gap.

Impulse Tests Made With a Cone-to-Disk Gap

The tests were made with a 45° cone disc gap, figure 2, with a spacing of 0.025″ using:

(*a*). Good oil
(*b*). Carbonized oil
(*c*). Wet oil

The tests were made with the time to crest at 0.5 m.s. and 8 m.s.

From these values a figure for 1.5 m.s. has been interpolated for use in connection with the standard impulse wave. Table II shows the ratio of dielectric strength values between the good oil taken as 1.00 and the carbonized and wet oils respectively. Each of the impulse values in table II was determined by making approximately 100 tests.

It will be observed that the presence of carbon or water in the oil does not affect the ratio under impulse conditions to the same extent as under steady state voltage conditions.

Tests Made With 60-Cycle Voltage on Large Spacings

Tests were made to determine how the variation in the dielectric strength of oil as measured by the standard gap is reflected in the dielectric strength of a larger assembly such as an oil circuit breaker; the equipment used in making these tests was described previously, and is shown in figure 3. High potential tests were made to determine what 60-cycle voltage could be held for one minute without breakdown or audible internal disturbance. Results are given in table III.

It will be observed that there is a much lower spread in the dielectric strength of oil in a large gap than might be anticipated from the spread in dielectric strength values with the standard gap.

Impulse Tests on Complete Oil Circuit Breakers With New and Old Oil

Impulse tests were made with a $1^1/_2$–40 m.s. positive wave on 12 complete oil circuit breakers to determine if the impulse strength of breakers would be appreciably lowered by carbon or water or both in the oil. The breakers were tested with new oil and then retested with old oil.

The new oil used to test breakers 1–10 inclusive was taken from standard package containers and tested 30 kv in a standard test cup.[3] The used oil with which these breakers were tested was taken from the dirty oil tanks in the high power laboratory and tested from 4 to 16 kv.

Breakers 1–10 inclusive were small three pole breakers with all three poles in a common tank. The results of the tests on these breakers are given in table IV which follows immediately.

Table IV. Tests on Complete Common Tank Breakers

Tests on Completed Circuit Breakers 1 to 10 Inclusive

Breakers Tested		Lowest Flashover (Kv) New Oil Testing 30 Kv	Lowest Flashover (Kv) Old Oil Testing 4–16 Kv	Highest Full Wave Withstood (Kv) New Oil Testing 30 Kv	Highest Full Wave Withstood (Kv) Old Oil Testing 4–16 Kv

" 10		127	127	148	148

All flashovers were outside of breaker.

Each of the above values is the lowest flashover or highest full wave of 15 tests.

Tests on Complete Circuit Breaker 11

Breaker 11 was a single pole of a three pole breaker with each pole in a separate tank. The bushings in this breaker had a higher than usual flashover strength in relation to the breakdown strength of the oil between the contacts and the tank. This condition made it possible to obtain breakdowns through the oil in the tank. The tests were made with the breaker closed and both bushings connected to the surge generator. The results of the tests with oils of different dielectric strength are contained in table V. All tests were made with a $1^1/_2$–40 m.s. positive wave.

Test on Complete Circuit Breaker 12

The tests on breaker 12 were made on poles 1 and 2 of a three pole high voltage frame mounted breaker with each pole in a separate tank. Pole 1 was filled with good oil testing between 26 and 27 kv. Pole 2 was filled with oil taken from breakers in service on the shop lines. This oil tested slightly under 19 kv. For convenience in table VI these oils are considered to have test values of 26 kv and 19 kv respectively. The tests made on breaker 12 and shown in table VI show the 26-kv oil to have a slightly higher impulse breakdown value than the

19-kv oil. This is contrary to the results obtained on breakers 1 to 11 inclusive and is probably due to the difference resulting from the two oils being tested in different tanks and on different poles of the breaker. All tests were made with the breaker open, one stud impulsed, frame and all other studs grounded. Approximately 15 seconds elapsed between tests. Both poles were tested and the results given in columns 1 and 2 of table VI. In these tests neither oil could be broken down. All flashovers—marked *F*—occurred in air over the outside end of the bushing. The poles under test were then changed by inserting 2″x$^1/_4$″ copper bar between the contacts and the tank cover to reduce the breakdown distance through the oil to the tank to 35% of the original distance. The tests in columns 3 and 4 were made and again the flashovers occurred through the air over the outer end of the bushing.

The breakdown distance through the oils was further reduced until it was only 19% of the original distance. Tests shown in columns 5 and 6 of table VI were then made. Breakdowns were obtained on pole 1 in good oil at a minimum of 245 kv. In pole 2 breakdowns were obtained through the 19-kv test oil at a minimum of 231 kv as indicated by the letter—*B*. All tests were made with a $1^1/_2$-40 m.s. positive wave.

Discussion of Test Results and Conclusions

The test data indicate that the presence in the oil of moisture, carbon, and other materials, normally tending to lower the 60-cycle dielectric strength of oil, appears not to change appreciably the ability of oil circuit breakers to withstand impulse voltages.

Table I shows that the impulse strength of large gaps in oil is practically constant for oils of different dielectric strength, within the range regularly used.

Table II shows that the impulse strength of small gaps in oil varies, but not directly, with the 60-cycle strength of the oil.

Table III shows that the 60-cycle breakdown strength of the breaker is reduced when the dielectric strength of the oil is lowered, but much less than in proportion to the loss of strength in the oils as measured in a standard oil test cup.

Table IV shows that the [4]impulse strength of ten small oil circuit breakers of different types and ratings was not lowered when they were tested with poor oil.

Data in table V, from tests made on a medium size outdoor breaker, show that the impulse strength of an oil circuit breaker might in some cases be better with poor oil than with good oil.

Data in table VI, from tests made on a large outdoor oil circuit breaker, show the impulse strength of large breakers to be practically unaffected by the 60-cycle strength of the oil within the range regularly used.

Oil for circuit breakers and transformers[4] is purchased with a minimum breakdown value of 22,000 volts. Since oil of this or higher strength is most easily obtained, the authors recommend that the oil used for high potential testing of oil circuit breaker, both 60 cycle and impulse, should have a dielectric breakdown strength of 22 kv or higher, the breakdown strength to be determined as prescribed by the American Society for Testing Materials.[3]

It is to be noted that apart from any reduction in dielectric strength resulting directly from the use of deteriorated oil as an insulating medium, there is a tendency for carbon particles to settle out from the oil upon insulating surfaces. This may in time decrease the creepage strength of these surfaces much more than the breakdown strength through the insulating medium is decreased, and constitutes the greatest danger from allowing poor oil to remain in the breaker. Consequently, the test results reported in this paper are not to be interpreted as suggesting any relaxation of maintenance activities in this respect.

Conductor Vibration—Theory of Torsional Dampers

JAMES W. SPEIGHT
NONMEMBER AIEE

Synopsis: The paper is a theoretical treatment of the torsional damper which has been applied effectively to the protection of transmission line conductors from fatigue failures due to aeolian vibrations. The formulae of the energy dissipation are derived for three cases, viz., a single rigid damper, two rigid dampers at one end of a span, and a single damper with a resilient joint at the centre of gravity. The results are valuable in understanding the mode of operation of the torsional damper and point to certain optimum features of design. The formulae can be used for numerical calculations when the physical constants are known.

Introduction

FOR many years, electric power companies have been investigating the protection of transmission line conductors from fatigue failures that result from the vibrations excited by steady cross winds of low velocity. The methods of protection that have been proposed are very diversified in character, including the prevention of the vibration at its source with conductors of non-circular cross section, the reduction of concentrated stresses at the clamp by the use of reinforcing cables or rods, and the suppression of the vibrations by the application of damping devices. An energy-absorbing damper has proven to be the most practical solution up to the present time, and has been adopted for a number of lines in North America. An estimate of the efficiency of such devices has been determined, in a few instances, by experimental field studies and, more frequently, by operating experience.

The Hydro-Electric Power Commission of Ontario with power lines of all sizes throughout the province has, of course, been vitally interested in the problem of aeolian conductor vibrations. The need for an effective solution has been most important in recent years since, in modern construction using long spans and high tensions, the conductor is subject to more severe conditions of vibration than in the older construction with short spans and low tensions. To study the effectiveness of various protective schemes, a method was devised for recording the natural vibrations of damped and undamped lines and for analyzing the results statistically. Such experimental data on the frequency characteristics of a type of conductor are essential for the proper design of a protective device for that particular type.

In the year 1935, the theoretical and practical studies indicated that the conductor itself was available to absorb energy, if a suitable restraining force could be applied to the conductor to utilize the interstrand friction and the mechanical hysteresis loss. This force was accomplished with an offset weight attached to the conductor by a horizontal arm, so that a torsional motion was produced between the suspension clamp and point of attachment of the weight when the conductor vibrated. Additional damping was obtained by mounting the offset weights in pairs adjacent to and at different distances from the suspension clamp, when, for most frequencies of vibration, the section of conductor between the two offset weights was also in torsional motion. The torsional device which has become known as a torsional damper has been developed considerably in the last five years and is now practical.

Torsional dampers have been installed for the suppression of aeolian vibrations on the latest ACSR lines built by the Hydro-Electric Power Commission of Ontario. A torsional damper designed for 795,000 cir-mil ACSR is shown in figure 1 and is constructed with a resilient joint of rubber. In California, a rigid type of torsional damper has been adopted for the protection of H-H copper conductor on the exposed sections of the Boulder Dam transmission line.

Theory

The theoretical development of the torsional damper was studied along with the experimental work, and it is the purpose here to derive the theoretical formulae. The formulae were of great assistance in bringing the torsional damper to its present form and are valuable in designing dampers for specific conductors and predicting the approximate performance. The analysis of the torsional damper is limited here to the condition of steady state vibration, and does not include other possible beneficial effects which might exist under initial transient conditions. The reaction of the damper on the motion of the conductor is not taken into account either, since, for the suppression of vibration, the energy dissipative capacity of the damper is of prime importance and is affected only by the amplitude of the motion at the point of attachment, all the other factors being constant. The application of the formulae to actual numerical cases is direct, provided that the requisite physical constants are available.

The mode of vibration at a given point of a line conductor in service usually has a beat characteristic and not a constant maximum amplitude. However, the generality of the analysis is not affected, if it is considered that the conductor vibrates like a perfectly flexible string under tension[1] having the motion

$$y = A_0 \sin (2\pi x/\lambda) \sin \omega t$$
$$= A \sin \omega t \qquad (1)$$

$$\alpha=q/2I \text{ and } \omega_c^2=\tau/I$$

the solution is

$$\theta=B_e^{-\alpha t}\sin(\omega t+\phi)$$

in which B and ϕ are constants and $\omega^2=\omega_c^2-\alpha^2$. If $\alpha\ll\omega_c$,

$$\omega^2\approx\omega_c^2=\tau/I$$

Therefore, the quantity q which will be defined as the "torsional resistance" is given by

$$q=\delta\tau/\pi\omega \tag{3}$$

because $\alpha=\delta f$ where δ is the logarithmic decrement.[3]

For a rod of circular cross section, the angular elastic constant is inversely proportional to the length of the rod.[2,3] Hence, it is evident from relation 3 that the torsional resistance of a conductor is increased by decreasing the length of the effective part of the conductor.

Single Rigid Damper

The position of a single rigid damper at any moment can be represented as in figure 2. The notation is

M = mass of damper
$I=MK^2/g$ = moment of inertia about the axis of the conductor
$I_G=Mk^2/g$ = moment of inertia about the centre of gravity
l = distance from the centre of conductor to centre of gravity
θ = angular displacement from the horizontal
$y=A\sin\omega t$ = displacement of the point of support
h = distance of centre of gravity from position of equilibrium
$K^2=k^2+l^2$

The velocity of the centre of gravity for small oscillations is $(\dot{y}-l\dot{\theta})$. Considering the transverse energy of the conductor to be independent of θ, the kinetic energy of the damper is

$$S=M(\dot{y}-l\dot{\theta})^2/2g+I_G\dot{\theta}^2/2$$

The potential energy associated with the torsional motion is

$$\tau(\theta+\theta_0)^2/2-\tau\theta_0^2/2=\tau\theta^2/2+Ml\theta \tag{4}$$

since θ_0 is the static rotation and $Ml=\tau\theta_0$. The increase in the gravitational potential energy of the mass is

$$Mh\approx M(y-l\theta) \tag{5}$$

Therefore, the potential energy function is, adding 4 and 5,

$$V=\tau\theta^2/2+My$$

The Lagrangian function is $L=S-V$ and, from Lagrange's equation[4]

$$\frac{d}{dt}\left[\frac{\partial L}{\partial\dot{\theta}}\right]-\frac{\partial L}{\partial\theta}=0 \tag{6}$$

it follows that, adding the dissipative term,

$$\ddot{\theta}+2\alpha\dot{\theta}+\omega_c^2\theta=l\ddot{y}/K^2 \tag{7}$$

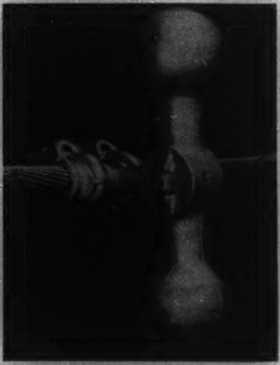

Figure 1. Torsional damper for 795,000-circular-mil steel-reinforced aluminum cable

The steady state solution of differential equation 7 is

$$\theta=-\frac{lA\omega^2}{K^2Z}\sin(\omega t-\beta) \tag{8}$$

with

$$Z^2=(\omega_c^2-\omega^2)^2+4\alpha^2\omega^2$$

and

$$\beta=\tan^{-1}[2\alpha\omega/(\omega_c^2-\omega^2)]$$

The power dissipation is

$$P=\frac{1}{T}\int_0^T q\dot{\theta}^2dt$$
$$=ql^2A^2\omega^6/2K^4Z^2 \tag{9}$$

The graph of the frequency function $f^6/[\pi^2(f_c^2-f^2)^2+\alpha^2f^2]$ contained in equation 9 for constant amplitude is plotted in figure 3 with $f_c=5$ cps. and $\alpha=4$. Actually, most materials dissipate energy by solid damping[3] and then δ, not α, is constant with respect to frequency. From the curve, it is seen that to suppress a range of frequencies the damper has to operate on the region above f_c, i.e.,

$$\omega_c<\omega \tag{10}$$

In determining the damper spacing, the amplitude A which is a function of the frequency is considered in conjunction with the other factors. As a numerical example, let the velocity of propagation (λf) be 400 ft./sec. and the damper be 5 feet from the clamp. For a frequency range 5 to 20 cps.,

$$1\geqq\sin(2\pi x/\lambda)>0.38$$

and the power loss at 20 cps. due to this factor is about seven times that at 5 cps. The magnitude of the divergence is reduced greatly, in practice, because the power loss associated with the transverse vibrations of a conductor excited by the wind increases rapidly with frequency and, consequently, the amplitude A_0 becomes smaller.[5] Thus, the spacing of 5 feet gives a satisfactory response to the frequency variations under these conditions.

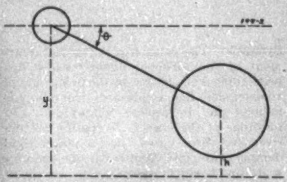

Figure 2. Schematic diagram of a single rigid damper in motion

If the condition $\omega_c\ll\omega$ is maintained, the optimum value of l is given by

$$\frac{d}{dl}(l^2/K^4)=0$$

or,

$$l=k \tag{11}$$

Then, the maximum power is

$$P_M=qA^2\omega^6/8l^2Z^2$$

from which it is deduced that the optimum optimum magnitude of l is the smallest value consistent with conditions 10 and 11.

For a damper with a heavy, concentrated mass and a long arm, $K\to l$; $\beta\to\pi$; $Z\to\omega^2$ and

$$\theta=(A/l)\sin\omega t$$

i.e., the centre of gravity remains stationary in space. This effect is observed in the field for the stated conditions. The power dissipation for this case, substituting the value of q, becomes

$$P=\delta_r f A^2/l^2$$

Two Rigid Dampers at One End of Span

In figure 4, the arrangement of two dampers having the same physical dimensions is shown schematically for the horizontal plane. The notation of the previous section is adopted with the subscripts 1 and 2 referring respectively to dampers 1 and 2. The quantities τ_1, τ_2 and τ_3 represent the angular elastic constants for the three sections of the conductor between the clamps and the two dampers. The displacements at the points of attachment are

$$y_1=A_1\sin\omega t$$

$$y_2=A_2\sin\omega t$$

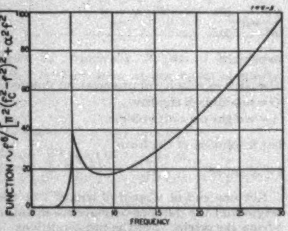

Figure 3. Graph of function for $f_c=5$ cycles per second and $\alpha=4$

The kinetic energy of the system is

$$S=(M/2g)[(\dot{y}_1-l\dot{\theta}_1)^2+(\dot{y}_2-l\dot{\theta}_2)]+I_G(\dot{\theta}_1^2+\dot{\theta}_2^2)/2 \quad (12)$$

Disregarding the gravitational potential energy function which does not contribute to the motion, the potential energy is

$$V=\tau_1\theta_1^2/2+\tau_3(\theta_1+\theta_2)^2/2+\tau_2\theta_2^2/2 \quad (13)$$

If the mutual torsional resistance is designated by q_3, the differential equations of motion with the dissipative terms are

$$\ddot{\theta}_1+2\alpha_1\dot{\theta}_1+\omega_1^2\theta_1+2\alpha_3\dot{\theta}_2+\Omega^2\theta_2=l\ddot{y}_1/K^2$$

$$\ddot{\theta}_2+2\alpha_2\dot{\theta}_2+\omega_2^2\theta_2+2\alpha_3\dot{\theta}_1+\Omega^2\theta_1=l\ddot{y}_2/K^2$$

with

$\omega_1^2=(\tau_1+\tau_3)/I$ and $\alpha_1=q_1/2I$

$\omega_2^2=(\tau_2+\tau_3)/I$ $\qquad \alpha_2=q_2/2I$

$\Omega^2=\tau_3/I$ $\qquad \alpha_3=q_3/2I$

Making the substitutions

$$N_1e^{j\beta}=A_1(\omega_2^2-\omega^2)-A_2\Omega^2+2j\omega(\alpha_2A_1-\alpha_3A_2)$$

$$N_2e^{j\gamma}=A_2(\omega_1^2-\omega^2)-A_1\Omega^2+2j\omega(\alpha_1A_2-\alpha_3A_1)$$

$$De^{j\epsilon}=(\omega_1^2-\omega^2)(\omega_2^2-\omega^2)-\Omega^4+4\alpha_3^2\omega^2-4\alpha_1\alpha_2\omega^2+2j\omega[\alpha_1(\omega_2^2-\omega^2)+\alpha_2(\omega_1^2-\omega^2)-2\alpha_3\Omega^2]$$

it follows that

$$\theta_1=-\frac{l\omega^2N_1}{K^2D}\sin(\omega t+\beta-\epsilon)$$

$$\theta_2=-\frac{l\omega^2N_2}{K^2D}\sin(\omega t+\gamma-\epsilon)$$

The power dissipated by the two dampers is

$$P=\frac{1}{T}\int_0^T[(q_1\dot{\theta}_1+q_3\dot{\theta}_2)\dot{\theta}_1+(q_2\dot{\theta}_2+q_3\dot{\theta}_1)\dot{\theta}_2]dt$$

$$=\frac{l^2\omega^6}{2K^4D^2}[q_1N_1^2+2q_3N_1N_2\cos(\beta-\gamma)+q_2N_2^2] \quad (14)$$

It is interesting to observe that the second term may increase or decrease the energy loss depending on whether N_1 and N_2 have the same phase or opposite.

If the moment of inertia is large and the arm is relatively long, the following approximations hold

$$\left.\begin{array}{l} N_1\rightarrow A_1\omega^2 \\ N_2\rightarrow A_2\omega^2 \\ D\rightarrow\omega^4 \\ K\rightarrow l \\ \beta\rightarrow\gamma\rightarrow\pi \\ \epsilon\rightarrow 0 \end{array}\right\} \quad (15)$$

Therefore, from equation 14,

$$P=\frac{\omega^2}{2l^2}(q_1A_1^2+2q_3A_1A_2+q_2A_2^2) \quad (16)$$

From relation 13 and the fact that the logarithmic decrement is equal to the energy loss per cycle divided by twice the maximum potential energy,[3] the power dissipation for conditions 15 may also be written

$$P=\frac{\delta f}{l^2}[(\tau_1+\tau_3)A_1^2+2\tau_3A_1A_2+(\tau_2+\tau_3)A_2^2] \quad (17)$$

The corresponding coefficients in expressions 16 and 17 are identical, so that the torsional resistances are

$$q_1=\delta(\tau_1+\tau_3)/\pi\omega$$

$$q_2=\delta(\tau_2+\tau_3)/\pi\omega$$

$$q_3=\delta\tau_3/\pi\omega$$

Single Damper With Resilient Joint at Center of Gravity

The inherent damping in some conductors is not sufficient in itself to suppress the vibrations adequately, even with two rigid dampers. Supplementary damping is introduced then by making a resilient joint near the centre of gravity with a material of high damping such as rubber. To facilitate the analysis, the damper is assumed to have the joint at the centre of gravity as in figure 5. In practice, the dampers are installed at both ends of the span and the power dissipation per span is twice the derived formula.

The notation will be the same as before with the subscript r designating the physical constants of the resilient material. The kinetic energy at any moment is

$$S=Mk^2\dot{\Phi}^2/2g+M(\dot{y}-l\dot{\theta})^2/2g$$

The potential energy is

$$V=\tau\theta^2/2+\tau_r(\Phi-\theta)^2/2$$

The damping force of the resilient joint is proportional to the relative angular velocity $(\dot{\Phi}-\dot{\theta})$. Hence, the differential equations of motion including the dissipative terms become

$$\ddot{\Phi}+2\alpha_r(\dot{\Phi}-\dot{\theta})+\omega_r^2(\Phi-\theta)=0 \quad (18)$$

$$\ddot{\theta}+2\alpha_N\dot{\theta}-2\alpha_r\frac{k^2}{l^2}(\dot{\Phi}-\dot{\theta})+\left(\omega_N^2\theta-\omega_r^2\frac{k^2}{l^2}(\Phi-\theta)=\ddot{y}/l\right)$$

where

$$\alpha_N=qg/2Ml^2$$

$$\alpha_r=q_rg/2Mk^2$$

$$\omega_N^2=\tau g/Ml^2$$

$$\omega_r^2=\tau_rg/Mk^2$$

But

$$y=A\sin\omega t$$

Therefore, making the substitutions

$$Q_1e^{j\mu}=\frac{A\omega^2}{l}(\omega_r^2-\omega^2+2j\alpha_r\omega)$$

$$Q_2e^{j\nu}=\frac{A\omega^2}{l}(\omega_r^2+2j\alpha_r\omega)$$

$$\Delta e^{j\zeta}=(\omega_r^2-\omega^2)(\omega_N^2-\omega^2)-\omega^2\omega_r^2k^2/l^2-4\alpha_N\alpha_r\omega^2+2j\omega[\alpha_N(\omega_r^2-\omega^2)+\alpha_r(\omega_N^2-\omega^2-\omega^2k^2/l^2)]$$

it follows that

$$\left.\begin{array}{l} \theta=-\dfrac{Q_1}{\Delta}\sin(\omega t+\mu-\zeta) \\ \Phi=-\dfrac{Q_2}{\Delta}\sin(\omega t+\nu-\zeta) \end{array}\right\} \quad (19)$$

The undamped natural frequencies of the damper are obtained by equating Δ, with the α-terms eliminated, to zero, i.e.,

$$f^4-f^2(f_N^2+f_r^2+f_r^2k^2/l^2)+f_r^2f_N^2=0 \quad (20)$$

The damper is designed so that the lower natural frequency is below the range of frequencies to be suppressed, as discussed in relation to figure 3. When the torsional resistance of the resilient material is greater than that of the conductor, the range of frequencies below the higher natural frequency of equation 20 will not be suppressed adequately if the mode of vibration about the conductor has the lower frequency. In such a case, it is necessary to decrease the frequency f_r of the mode associated with the resilient material.

The rate of energy dissipation is

$$P=\frac{1}{T}\int_0^T [q\dot{\theta}^2+q_r(\dot{\theta}-\dot{\Phi})^2]dt$$

$$=\frac{\omega^2}{2\Delta^2}[qQ_1^2+q_r\{Q_1^2+Q_2^2-2Q_1Q_2\cos(\mu-\nu)\}] \quad (21)$$

The last term approaches a maximum contribution as $(\mu-\nu)\rightarrow\pi$, and its minimum as $(\mu-\nu)\rightarrow 0$. For an undamped condition, equation 18 can be written

$$(\omega_r^2-\omega^2)\Phi=\omega_r^2\theta$$

It is evident that $\theta=-\Phi$ is possible, in this case, only at one frequency, viz., $f=\sqrt{2}f_r$. The relation $\theta=\Phi$ can exist if $f=0$ or ω_r is very large. The first condition is not satisfied; the second is present for a large τ_r and the device would be a rigid damper. Consequently, the resilient joint has a dissipative effect at all operating frequencies, although it reaches a maximum displacement only at a unique frequency.

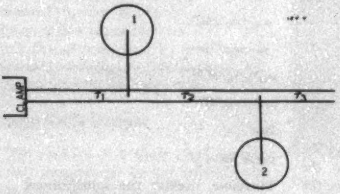

Figure 4. Schematic arrangement of two rigid dampers at one end of a span (horizontal plane)

For a large mass, which is necessary to obtain the low undamped natural frequency, and a high conductor frequency, the following approximations hold:

$$Q_1\rightarrow A\omega^4/l$$
$$Q_2\propto\omega^3$$
$$\Delta\rightarrow\omega^4$$
$$\mu\rightarrow\pi$$
$$\nu\rightarrow\pi/2$$
$$\zeta\rightarrow 0$$

With these values, equations 19 and 21 become

$$\Phi\approx 0$$

$$\theta=(A/l)\sin\omega t$$

$$P=\frac{\omega^2A^2}{2l^2}(q+q_r)$$

Using the mathematical reasoning of the previous section and relation 3, it can be shown that

$$q=\delta\tau/\pi\omega$$

$$q_r=\delta_r\tau_r/\pi\omega$$

Physical Constants

The logarithmic decrement and angular elastic constant are required for numerical computations and can be found experimentally, in one way, from the decrement curves of free torsional motion.

To illustrate the magnitude of these quantities: For a 795,000 cir-mil ACSR, $\delta\approx 0.19$ and τ per foot varies from 230 lb.-ft./rad. at 3,000 pounds tension to 360 lb.-ft./rad. at 5,700 pounds tension. For a 336,000 cir-mil ACSR, $\delta\approx 0.20$ and τ per foot is 46 lb.-ft./rad. at 1,200 pounds tension increasing to a constant value of 78 lb.-ft./rad. at approximately 3,600 pounds tension.

Summary

In the theoretical treatment of the torsional damper, the following conclusions pertaining to the general design of dampers have been deduced:

1. The angular elastic constant and, thus, the torsional resistance are inversely proportional to the length of effective conductor.
2. The undamped natural frequency of the damping system has to be below the lowest prevalent conductor frequency to be suppressed.
3. The damper is placed at the point of highest amplitude, consistent with maintaining a low natural frequency and a high torsional resistance. The effect of amplitude variations over the frequency band on the determination of spacing is not very critical, because the damper has to be effective over such a large range of loop lengths (possibly 5 to 50 feet).
4. For a rigid damper, the distance from the centre of the conductor to the centre of gravity should be as short as possible and equal to the radius of gyration about the centre of gravity. The damper, applied singly, should be placed near the clamp and still satisfy conclusions 2 and 3.
5. With the arrangement of figure 4, the two rigid dampers are mounted in the same loop in order to take advantage of the mutual dissipation. The optimum spacings, which will be short for large torsional resistances, could be determined by calculation for specific cases.
6. The single damper with a resilient joint is required for conductors having a small damping capacity. This type of damper has an advantage over the rigid type in that the damping factor of the resilient material can be varied, whereas that of the conductor is fixed. The spacing for this device is found in the same manner as for the rigid damper. As an example, the torsional damper of figure 1 is installed 6 feet from the clamp on 795,000 cir-mil ACSR.

Appendix

The rigid analysis of the motion of a single rigid damper will be developed to show that the above solutions are approximations strictly valid for short spans.

The torsional wave equation

$$\frac{\partial^2\theta}{\partial t^2}=a^2\frac{\partial^2\theta}{\partial x^2}$$

in which

$a^2=Gg/\gamma=$ velocity of propagation squared
$G=$ modulus of rigidity
$\gamma=$ weight per unit volume

has a solution of the form

$$\theta=X\sin\omega t$$

Let one end of a span of length s be the origin and the damper be placed a distance b from the origin. For the end conditions

$$\theta=0 \text{ at } x=0 \text{ and } x=s,$$

the space function can be written

$$X_1=C\sin\frac{\omega x}{a}: \qquad 0\geq x\geq b$$

$$X_2=D\sin\frac{\omega(x-s)}{a}: \quad b\geq x\geq s$$

The conditions to be satisfied at $x=b$, with I_p representing the moment of inertia of the area of cross section of the conductor, are

$$\left.\begin{aligned}&\theta_1=\theta_2\\&I\frac{\partial^2\theta_1}{\partial t^2}=-GI_p\left[\frac{\partial\theta_1}{\partial x}-\frac{\partial\theta_2}{\partial x}\right]\end{aligned}\right\}\quad (22)$$

Eliminating C and D, the natural frequencies are given by

$$\tan\frac{\omega(b-s)}{a}\left[\tau'\cot\frac{\omega b}{a}-a\omega I\right]=\tau'$$

where

$$\tau'=GI_p$$

For a practical installation, $s\gg b$ and b is small. Then, with $\beta=\omega s/a$,

$$\tan\beta=\frac{\tau'b\beta}{\beta^2a^2bI/s-\tau's} \quad (23)$$

having consecutive roots $\beta_i(i=1, 2, 3 \ldots .)$.

When β has a value such that $\tan\beta \rightarrow \beta$, the natural frequency becomes

$$\omega_c^2 \approx \tau'/bI \tag{24}$$

which agrees with the approximate theory.

For forced oscillations, the solution in generalized co-ordinates is

$$\theta_1 = \sum_{i=1}^{i=\infty} x_i \sin\frac{\beta_i x}{s}; \qquad 0 \geq x \geq b$$

$$\theta_2 = \sum_{i=1}^{i=\infty} x_i \left(\frac{D}{C}\right)_{\substack{\beta=\beta_i\\ x=b}} \sin\frac{\beta_i(x-s)}{s}; b \geq x \geq s$$

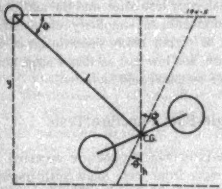

Figure 5. Schematic diagram of a damper with a resilient joint at the center of gravity

The potential energy function is

$$V = \frac{\tau'}{2}\left[\int_0^b \left(\frac{\partial\theta_1}{\partial x}\right)^2 dx + \int_b^s \left(\frac{\partial\theta_2}{\partial x}\right)^2 dx\right]$$

$$= \tau'\beta_i(A_i+B_i)x_i^2/8S^2$$

with

$$A_i = 2\beta_i\left[b-(b-s)\left(\frac{D}{C}\right)^2_{\substack{\beta=\beta_i\\ x=b}}\right]$$

$$B_i = s\left[\sin\frac{2\beta_i b}{s} - \left(\frac{D}{C}\right)^2_{\substack{\beta=\beta_i\\ x=b}} \sin\frac{2\beta_i(b-s)}{s}\right]$$

The kinetic energy function is

$$S = \frac{\gamma I_p}{2g}\left[\int_0^b \left(\frac{\partial\theta_1}{\partial t}\right)^2 dx + \int_b^s \left(\frac{\partial\theta_2}{\partial t}\right)^2 dx\right] + \frac{I_G}{2}\dot{\theta}_{x^2=b} + \frac{M}{2g}(\dot{y}-l\dot{\theta})_{x^2=b}$$

$$= \left[\frac{\gamma I_p(A_i-B_i)}{8g\beta_i} + \frac{I_G}{2}\sin^2\frac{\beta_i b}{s}\right]\dot{x}_i^2 + \frac{M}{2g}\left(\dot{y} - l\dot{x}_i \sin\frac{\beta_i b}{s}\right)^2$$

Applying Lagrange's equation, the differential equation for x_i is:

$$\left[\frac{\gamma I_p(A_i-B_i)}{4g\beta_i I} + \sin^2\frac{\beta_i b}{s}\right]\ddot{x}_i + \frac{\tau'\beta_i(A_i+B_i)}{4I_g^2} x_i = \frac{l\ddot{y}}{K^2}\sin\frac{\beta_i b}{s}$$

For the condition $\tan\beta \rightarrow \beta$

$$A_i \rightarrow B_i \rightarrow 2\beta_c b$$

and the differential equation simplifies to

$$\left(\sin\frac{\beta_c b}{s}\right)(\ddot{x}_c + \omega_c^2 x_c) = l\ddot{y}/K^2$$

Hence, for $K \rightarrow l$ and $\omega \gg \omega_c$

$$\theta_{x=b} = (A/l)\sin\omega t$$

The general solution of torsional dampers with the damping constants is obviously complex. The single natural frequency of the approximate solution is replaced by a series of frequencies in the general solution of a long span, since the distributed mechanical system of the conductor becomes a major part of the vibratory system. However, the lowest natural frequency of equation 23 is less than that of equation 24 for long spans and a damper designed for the approximate conditions will be effective when $\tan\beta \neq \beta$.

The Protection of Solid Insulation by Lightning Arresters

D. D. MacCARTHY
ASSOCIATE AIEE

T. J. CARPENTER
ASSOCIATE AIEE

Introduction

THE protection of distribution transformers or other apparatus against lightning involves the basic problem of limiting the voltage applied to the insulation to a value adequately below the insulation strength. The effect on insulation of chopped waves and full waves of standard impulse wave shapes such as 1.5x40 microseconds has been thoroughly investigated in the past. However, there has been a lack of the information necessary to compare the effect of chopped waves with the effect of voltages of other than standard wave shape resulting from arrester breakdown followed by the impedance drop that occurs during the impulse current discharge. Also there have been little data available on the failure of low voltage insulation. For these reasons an investigation has been made using oil immersed solid insulation of a type used in distribution transformers. The puncture voltage and number of shots to failure were determined when the insulation was in parallel with lightning arresters or gaps which controlled the wave shape of the voltage applied to the insulation. These results have been correlated with the single shot puncture voltage determined from tests in which failure occurred on the wave front. It was found that repeated applications of voltages in excess of approximately 70 per cent of the single shot puncture voltage may damage the insulation.

Insulation Samples

The insulation tested consisted of pads of 10- by 10-inch sheets of kraft paper 5 mils in thickness. Thin sheets of paper were used so that the failure voltage could be varied in small steps by changing the number of sheets in series. The line electrodes were pancake coils 2 inches in outer diameter and 1 inch in inner diameter wound from 85- by 155-mil copper, see figure 1. The turns of the line electrodes were wrapped with paper insulation of a type used in transformers. This insulation raised the corona voltage and made the failure voltage of the insulation pads less erratic. The turns of the coils were tied with 15-mil thread since thread and tape are sometimes used on transformer coils. The maximum thickness of the coil insulation at points of contact with the paper was about 20 mils but was variable due to the thread and the paper wrapping. At the ends of the coil, the copper strips were bent perpendicular to the plane of the coil and brought up through a 15-lb cylindrical weight 2 inches in outside diameter used to assure good contact. These leads were connected in parallel to the impulse generator. The pads were immersed in transformer oil in a metal tray that served as the ground electrode. Both the coils and the paper were vacuum treated and oil impregnated before the tests to eliminate moisture and absorbed air. The samples were kept under oil at all times until failure. Although all of the materials in the pads are used for certain types of insulation in transformers, the pads as tested cannot be considered[1] as representing the actual insulation strength of transformers, since in transformers steep impulse waves may result in an unequal distribution of voltage along the turns and the major insulation does not consist of paper sheets alone. In designing the insulation test pieces, it was necessary to consider the requirement of simulating transformer insulation and the additional requirements of simplicity of construction to permit ready observation of the failure, and low cost so that a large number of samples could be tested.

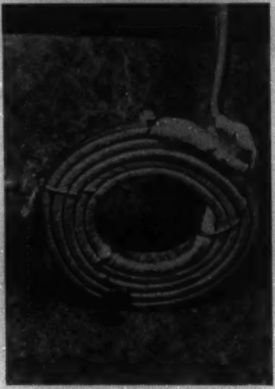

Figure 1. Insulation sample after puncture

A line electrode turned on edge to expose puncture and a small section of the sheet of 10- by 10-inch kraft paper used are shown. The bottom of an oil-filled metal tray formed the ground electrode

Single-Shot Puncture Tests

Tests in which puncture occurred on the wave front were made with impulse voltages of negative polarity that rose at a uniform rate until chopped by insulation puncture. A new line electrode and new sheets of paper were used for each test. The puncture voltage and time were determined, by means of cathode ray oscillograms, see figure 2, for line electrodes alone and line electrodes in series with pads of two, five, and eight sheets of paper. As the thickness of the insulation pads was changed the constants of the impulse generator circuit were adjusted so as to produce puncture at approximately the desired time. In those cases where the wave initially departed from a uniform rate of rise, the virtual zero was determined by a chord through the 30 and 90 per cent points on the voltage oscillogram. The results are plotted in figure 3. The failure in all cases was due to puncture through the paper and tended to occur near the outside of the line electrodes; corona was observed during tests of pads with five and eight sheets of paper.

Since it is desirable to base average curves on all of the available test data, the test results were correlated by means of figure 4 in which the average puncture voltage for failure times of 0.2, 1, and 8 microseconds was plotted against the paper thickness. The solid line curves of figure 3 give the puncture voltage from tests on line electrodes alone and pads with two, five, and eight sheets of paper; all of the original data points were plotted. The broken line curves for three, four, six, and seven sheets were obtained by interpolation from figure 4.

From figure 3 the puncture voltage at

Paper 41-133, recommended by the AIEE committee on protective devices, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 15, 1941; made available for preprinting May 15, 1941.

D. D. MacCarthy and T. J. Carpenter are both with the lightning arrester engineering department, General Electric Company, Pittsfield, Mass.

[1] For all numbered references, see list at end of paper.

0.25 microsecond is about 116 per cent of the value at 1 microsecond. Tests by Montsinger[1] gave a ratio of 160 per cent for the failure voltages at the same value of time. It is suggested that this difference is due to the considerable differences in the structure of the insulation samples tested in the two investigations and to differences in the applied voltage waves. Montsinger's tests were made on insulation barriers 0.64 and 2.5 inches in total thickness with relatively large oil ducts; the samples were designed to simulate the major insulation used in high voltage transformers.

From figure 4, it is evident that the average puncture voltage increased linearly with the total thickness of the paper sheets in the pad. This is evidence that the strength of the individual paper sheets and the distribution of voltage were uniform. Although the line electrode insulation measured 20 mils in thickness including the thread, it had a puncture voltage equivalent to 7.5 mils of the 5-mil paper. Failure tended to occur at the threads presumably due to a concentration of stress.

Puncture of Insulation in Parallel With Arresters or Gaps

A second series of tests was made with pads in parallel with 9-kv distribution arresters or gaps set for values of impulse breakdown within the range permitted by lightning protective devices used on 6,900-volt circuits. Several types of gaps were used among which were $^1/_2$-inch square rod gap set at $^{61}/_{64}$ inch and $2^1/_{16}$ inches; and sphere gaps 6.25 centimeters in diameter set at 16 millimeters. Cathode ray oscillograms were taken to show the failure voltage and time, see figure 5. A new line electrode and new sheets of paper were used for each test but not for each impulse. Although the applied impulse voltage wave was changed during the series of tests, each individual sample was punctured by repeated applications of the same voltage wave except that the tests were stopped in three cases after 100 or more shots. A total of 95 pads was tested and the results are summarized in the tabulation. In all tests the applied voltage rose at an approximate rate of 500 kv per microsecond until reduced by the arrester or gap or by puncture of the insulation. The rate of 500 kv per microsecond exceeds the rate of 100 kv per microsecond recommended in the appendix to "Standards for Testing Lightning Arresters," ASA C-62, and is perhaps representative of the steeper rates to which distribution arresters in service are subjected. The gap and arrester breakdown voltages in the tabulation exceed the values obtained from tests with voltages rising at 100 kv per microsecond. For example the 9-kv valve type arresters have a breakdown voltage of approximately 50 kv on the 100 kv per microsecond tests whereas a breakdown of 69 kv is given in the table for the 500 kv per microsecond wave. The time to breakdown of the arresters or gaps ranged from 0.13 to 0.30 microsecond on the 500 kv per microsecond wave. These values of time to breakdown of the arresters or gaps are small compared to the range of one to four microseconds required for the *IR* voltage to reach crest and are still smaller in comparison with the duration of the *IR* voltages produced by current discharges that decayed to half value in 40 microseconds.

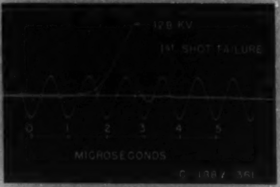

Figure 2. Volt-time oscillogram taken during single-shot puncture tests on eight sheets of 0.005- by 10- by 10-inch paper

When arresters were used, the impulse current had a crest of 5,000 amperes, an initial rate of 2,200 amperes per microsecond, and a time to half value of 40 microseconds. The value of 5,000 amperes crest was chosen for the current since 88 per cent of the discharge currents measured[2] through rural distribution arresters in service did not exceed this value. While comparatively little information is available[3] on rates of rise and duration of currents discharged by arresters in service, it is believed that the impulse discharge used in these tests was of more than average severity.

When gaps were tested, the impulse discharge current crest was 500 amperes or less and the time to half value was 40 microseconds. The value of approximately 500 amperes was selected for the magnitude of the discharge current as a matter of convenience and to give arc voltages and inductive drops that were small. For part of the tests, wire-wound resistors of 120 to 150 ohms were connected in series with the gaps to study the effect of *IR* voltage on insulation failure. Cathode ray oscillograms, see figure 5, showed whether the insulation failure occurred as the voltage was rising to gap breakdown or during the subsequent application of *IR* voltage to the insulation.

Comparison of Test With and Without IR Voltage

By means of the data in the tabulation, it is possible to compare the effect on insulation failure of breakdown voltage without subsequent *IR* voltage, with the effect of breakdown voltage followed by *IR* voltage. The per cent of single shot puncture voltage given in the tabulation is the ratio of the breakdown or *IR* voltage applied to the pad to the average single shot voltage determined from figure 3 for a pad with the same number of sheets. When valve arresters were tested the crest *IR* voltage occurred at one to two microseconds so the single shot puncture voltage curves were read at 1.5 microseconds; the wire-wound resistors gave crest *IR* voltages at two to four microseconds, and the curves were read at 3.0 microseconds. In tests 1 and 2 with valve type arresters puncture always occurred as the voltage was rising to gap breakdown; two-sheet pads failed in 1 to 5 shots and three-sheet pads in 3 to 14 shots. In test 3 with gaps set for

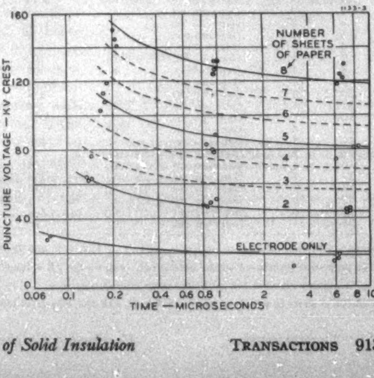

Figure 3. Volt-time curves for single-shot puncture from front-of-wave tests

The solid lines are the average volt-time curves from the original data as correlated by figure 4. All original data are plotted

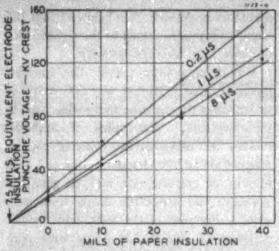

Figure 4. Average single-shot puncture voltage from front-of-wave tests

nearly the same impulse breakdown as in tests 1 and 2 but having no *IR* drop, two-sheet pads failed in one shot. In test 4, six of the three-sheet pads failed in one to nine shots (see footnote in tabulation) and the seventh pad withstood an abnormal number of shots. A comparison of tests 1 and 2 with tests 3 and 4 shows that valve arrester *IR* drops of 74 and 58 per cent of the average single shot puncture voltage did not reduce the number of shots required to fail the insulation.

However, it is evident that the *IR* voltage if sufficiently high will reduce the number of shots the insulation can withstand. This is seen from tests 4, 5, and 6 and tests 7, 8, and 9. The gap breakdown voltage was approximately equal for the three tests 4, 5, and 6. Test 4 was made with no *IR* voltage. In test 5 the *IR* voltage was 84 per cent of the single shot strength and puncture occurred on the *IR* voltage in two out of the seven tests. In test 6 with an *IR* voltage of 95 per cent of the single shot strength, puncture always occurred on the first shot during the *IR* voltage. These tests indicate that repeated shots with *IR* voltages in excess of 84 per cent of the single shot strength will deteriorate the insulation.

The three tests 7, 8, and 9 were all made with the same gap and give additional information on the effect of *IR* voltage. In test 7 there was no *IR* voltage and two pads each withstood 102 shots. In test 8 the *IR* voltage was 69 per cent of the single shot failure voltage and three of the pads tested punctured on shots 25, 34, and 86 while the fourth pad withstood 109 shots without failure. Although it might be inferred from a comparison of tests 7 and 8 that the *IR* voltage reduced the number of shots to fail the insulation, the number of pads are so few in test 7 and the range of shots so large in test 8 that such a deduction is questionable. On test 9 the *IR* voltage was 78 per cent of the single shot puncture voltage and failure occurred in fewer shots than in tests 7 and 8.

The remainder of the tabulation shows the number of shots required to puncture pads with various amounts of insulation when the voltage was chopped by gaps without series resistance. The protective ability of these gaps was approximately equivalent to a rod gap set two inches, since the breakdown voltages ranged from 112 to 125 kv and there was no *IR* voltage. With these gaps in parallel with the pads, it was necessary to have from five to eight sheets in the pads to withstand the same number of shots as were withstood by pads with two or three sheets when tested in parallel with valve arresters that had a breakdown voltage of 69 kv and an *IR* voltage of 34-kv crest.

Effect of Repeated Shots on Insulation Puncture

Thus far comparisons have been made between part of the individual tests listed in the tabulation. However, the effect of repeated shots can best be determined by putting the data from all tests on a common basis. This has been done in figure

NOTES: [a] Number of shots to puncture pads: 1, 1, 1, 2, 4, 9, and 78.

[b] Five pads were punctured on the breakdown; two on the *IR* voltage.

[c] Two samples withstood 102 shots and tests were discontinued.

[d] Number of shots to puncture pads: 25, 34, 86, and one withstood 109 shots.

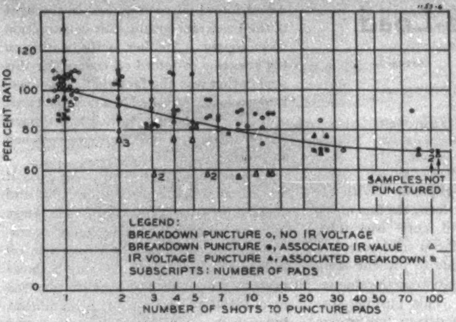

Figure 6. Tests with repeated shots

The applied voltage, in per cent of the single-shot puncture voltage, is plotted against the number of shots to puncture the pads. The insulation pads were in parallel with gaps or arresters

6 where the applied voltage expressed in per cent of the single shot puncture voltage was plotted against the number of shots to rupture the insulation. Data points were plotted from each of the 95 pads tested whereas the tabulation was condensed to include only averages or the ranges of data. A point was plotted for arrester or gap breakdown voltage and another for the *IR* voltage when it existed. The symbols indicate whether the puncture occurred as the voltage rose to gap breakdown or during the subsequent *IR* voltage. Since a large number of insulation punctures occurred on the first few shots, these points have been grouped about the ordinate through the actual shot number. Factors responsible for the scattering of the points include variations in the gap or arrester breakdown voltages, variations in the impulse generator discharge from shot to shot, and variations in the puncture voltage of individual pads.

The curve in figure 6 shows that the number of shots required to fail the insulation increases as the applied voltage expressed in per cent of the single shot puncture voltage is reduced. In all tests in which the insulation was ruptured, either the breakdown or the *IR* voltage was at least 70 per cent of the single shot puncture voltage. It is concluded from this plot that the insulation will withstand a large number of repeated shots provided the applied voltage does not exceed a value of approximately 70 per cent of the single shot puncture strength at any value of time. Within the limits of this investigation, this conclusion holds irrespective of whether the applied voltage is of short or long duration. On the basis that the curves of figure 3 are 100 per cent, it is concluded that curves drawn through 70 per cent of the voltage will approximate the shape of the highest voltage wave that can be repeatedly applied without reducing the number of shots the insulation will withstand. Montsinger[1] found that repeated shot injurious corona appears at voltages of 65 to 90 per cent of the single shot failure voltage and concluded that 80 per cent is a safe average value of voltage for repeated shots. The value of 70 per cent from the present tests is in good agreement with his results notwithstanding the differences in the structure of the insulation tested in the two investigations.

The Effect of Voltage Wave Shape on Insulation Puncture

One object of this investigation was to determine if arrester *IR* voltages of relatively low magnitude might possibly be more destructive to insulation because of long duration than voltages of relatively short duration preceding the breakdown of gaps. This was not found to be the case in these tests. The higher voltages necessary to puncture the insulation samples at short values of time are due to turn up of the insulation volt-time characteristic. Although figure 3 shows that higher voltages are required to cause puncture in short values of time, this might be offset in transformers by nonuniformity in distribution of voltage between the turns of the transformer coils which increases with the steepness of the voltage applied. Although these tests on insulation samples showed no evidence of deterioration of the insulation due to voltages less than 70 per cent of the single shot strength, the conclusion should not be drawn that chopped waves of this magnitude are necessarily harmless to turn insulation in actual transformers.

Conclusions

(1). The single shot puncture of the insulation increased linearly with the insulation thickness over the range tested in this investigation.

(2). The single shot volt-time puncture curves of the insulation tested in this investigation are relatively flat; the average puncture voltage for failure at 0.25 microsecond was found to be only 16 per cent more than the puncture voltage at 1 microsecond.

(3). This investigation shows that valve type arresters, of the type tested and the rating applied on 6,900-volt circuits, are superior to two-inch rod gaps for the protection of insulation when subjected to impulse discharges that are of more than average severity based upon field records.

(4). Tests with repeated applications of impulse voltages showed that as the ratio of the applied voltage to the single shot puncture voltage is reduced, the number of shots necessary to rupture the insulation increases.

(5). The insulation tested withstood a relatively large number of shots provided the applied voltage did not exceed a value of approximately 70 per cent of the single shot puncture voltage at any instant of time during the application.

(6). From life tests during which the insulation was subjected to voltage waves modified by the operation of protective devices, it is concluded that the insulation will withstand a relatively large number of shots provided the instantaneous voltage due to breakdown or *IR* voltages does not exceed approximately 70 per cent of the single shot puncture voltage.

(7). The results of this investigation suggest that in the application of protective devices, the upper limit of the stress that can be safely applied repeatedly to new insulation may be regarded as 70 per cent of the single shot puncture voltage; this is irrespective of whether the highest stress permitted by the protective devices is due to short or long time gap breakdown or short or long duration *IR* voltages.

A New Transformer for Base-Load Stations

PHILIP SPORN
FELLOW AIEE

H. V. PUTMAN
MEMBER AIEE

Synopsis: This paper describes the application of Hipersil to three 40,000 Kv-a units for the Philo generating station of The Ohio Power Company. Because of Hipersil's ability to carry one-third more magnetic flux, appreciable savings in weight and dimensions are possible—in fact, the transformers will be shipped in oil completely assembled with bushings in place, ready to operate.

Forced-oil and forced-air cooling are provided, with proper relays for protection in the event of excessive copper temperature or failure of auxiliaries. Reliability, economy, ease of installation, and low maintenance have been the objectives sought in the design.

ALTHOUGH technical progress in the art of transmission of electrical energy has been considerable in the last two decades, it is a fact that no single significant contribution looking toward more economical transmission is readily called to mind. Most particularly is this true in the case of the transformer—the essential link in a-c transmission. Thus, major design and construction improvements have been made in impulse strength, in lightning protection, and in impulse testing of transformers. But these developments have only indirectly affected cost. Even more notable is the fact that a design trend of many years background in the direction of continually reducing losses has not been re-examined, nor most certainly altered in the face of decreasing costs of electrical capacity and energy. The development described here, it is believed, marks a definite step in altering that condition.

The essential element in this new design is a new steel, Hipersil.[1] Its outstanding characteristic is its ability to carry approximately one-third more magnetic flux in the transformer core. Figure 3 shows equipment used in a test made on two model cores identical in size—one of silicon steel and one of Hipersil. With the same exciting ampere-turns the flux measured in the Hipersil core was 38% greater than in the silicon steel core. It is hoped at a later date to present some more extensive information on the characteristics of Hipersil. This pushing forward of some of the design limitations which have heretofore held in check transformer designers, even though, for the present at least, the advantages of the new material must be limited to transformers where it can be used with the magnetic flux in line with the direction of rolling, is bound by itself to have a most material effect on transformer design economics and on transformer design art. In the development described, Hipersil has been coupled with forced-oil cooling, and with re-examined criteria for losses in the light of modern power and energy economics. But safety and reliability, as will be evident from the more detailed description to follow, have not been sacrificed.

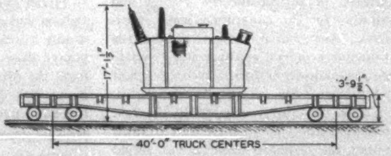

Figure 1. 40,000-kva 138-kv transformer mounted on standard flat car for shipment

In spite of the large size of this transformer, it will be shipped completely assembled with cooling equipment, oil bushings, and lightning arresters in place

Description of Transformer Units

This paper presents specifically the results of an analysis to see what the possibilities of this new material and new ideas would be in the design of large transformers for a base load station. The particular units under consideration are rated 40,000 Kv-a, 138 Kv, with non-solidly grounded neutral. The relatively lower cost of energy at the station bus was fully considered in evaluating the transformer losses and it made possible a closer use to the full of the inherent properties of Hipersil in reducing dimensions and the amount of active material required.

It was found that the smaller weights and dimensions resulting from the greater flux carrying capacity of Hipersil could be reduced still further through the use of forced-oil cooling, and in the light of the basic aim sought, this construction was adopted. Another factor bearing on the selection of forced-oil cooling for this application was the fact that little overload capacity is needed in a base load unit operating on the unit principle with generator and transformer in series switched as a unit.

As a result of these two basic ideas it was found possible to reduce weights and dimensions to a point where these large transformers could be completely assembled in the factory to be shipped in oil with bushings in place. Figure 1 shows an elevation of one of these units mounted on a standard flat car with significant dimensions. The cost of erection and starting in the field will obviously be reduced to a minimum.

Another interesting feature of these transformers is that due to the small size and the relatively small amount of oil involved it was possible to weld the cover on and seal the unit permanently against deterioration of the oil and insulation. There is no provision for breathing.

When operating at full load, these transformers have oil circulating pumps and fans in continuous operation, but much thought has been given to the question of reliability and protective devices. It is believed that with the arrangements described below, a degree of reliability comparable with that of other major apparatus in the generating station has been obtained.

It is interesting to examine the reduction in weights and increase in losses of this transformer compared with a standard self-cooled air-blast unit of the same rating:

Copper windings	reduction in weight	10%
Core	reduction in weight	25%
Losses	increase in weight	5%

Cooling System

The transformer itself is of shell-type construction and is mounted horizontally in the tank. Fin-type coolers employing round tubes of substantial cross-section are mounted on each side of the tank wall and provided with circulating pumps and cooling fans. The two radiator assem-

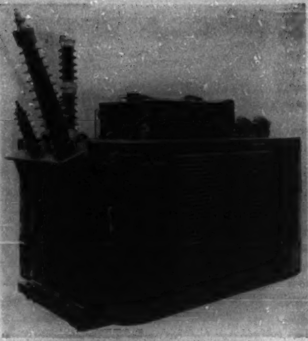

Figure 2. Side elevation of 40,000-kva 138-kv transformer showing principal over-all dimensions

The transformer is completely sealed with cover welded in place. No auxiliary gas equipment is required since adequate gas space is provided in the tank for maximum expansion and contraction due to temperature changes

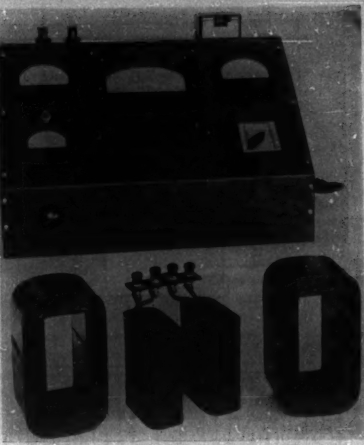

Figure 3 (right). Test to demonstrate flux-carrying capacity of Hipersil

Two cores identical in size—one silicon steel, one Hipersil—were excited with 0.5 ampere through a coil of 154 turns. The voltage across the coil when assembled on the silicon steel core was 92—when on the Hipersil core, 127. Since the flux produced in the core is proportional to the voltage, the Hipersil core carried a flux greater than the silicon steel, in the ratio of 127 to 92, or approximately 38 per cent greater

blies are operated as independent units. Power for the pumps and fans is supplied from two auxiliary transformers mounted inside the main unit—one auxiliary transformer taking care of one radiator bank. However, each of these auxiliary transformers is of sufficient capacity to supply power for the pumps and fans of both cooling units, and the control is so arranged that in the event one auxiliary transformer should fail, its fans and pump can be immediately connected to the other transformer. The control, too, is so arranged that both oil circulating pumps operate at no load but the fans come on as required; that is, when the oil temperature reaches 65°C, one set of fans comes into operation; at 75°C, the second set of fans comes into play.

Differential pressure relays are provided on each circulating pump. With only one pump in operation the capacity of the transformer would be reduced to 80%. Should the oil flow stop through one of the coolers due to failure of the pump or any other cause, the differential pressure relay would sound a warning to the station operator. Should both pumps stop, a signal to clear the unit from the line is given.

Operation by Copper Temperature

Since the thermal capacity of these transformers is small—comparatively little oil being required—excess copper temperatures could be reached in a relatively short time in the event difficulty should develop in the cooling system. For this reason relays are provided in each unit which operate on copper temperature. At 105 degrees centigrade copper temperature (measured by resistance), a warning signal is sounded to the station operator indicating that steps should be taken to reduce the load. It is not likely that the transformers would be actually overloaded due to the limitation of the generating equipment in the station, but it is conceivable that in the event of failure of fans or pumps on one side of the unit, even normal full load would exceed its reduced load carrying capacity. Should the copper temperature continue to increase and reach a dangerous point, the copper temperature relay signals the station operator for immediate shut-down.

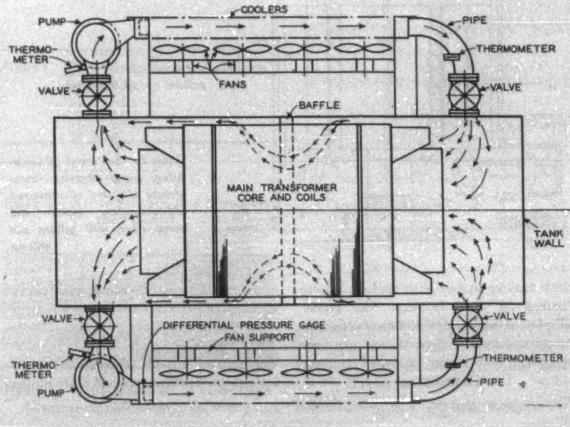

Figure 4. Plan view showing oil circulation system

Pumps and fans are arranged in two independent assemblies each supplied from a separate auxiliary transformer mounted inside the main tank. Protection to the unit is provided in the event of failure of pumps by means of differential pressure relays and in the event of fan failure by copper temperature relays

Fans and Pumps

A number of different blower arrangements were attempted during the course of the design but the use of simple air-

blast fans equipped with motors having "sealed for life" bearings was finally adopted as the simplest and most economical arrangement. Sixteen fans are employed on each cooler, mounted in racks of four. Consideration has been given to easy replacement of these individual racks should that become necessary as a matter of routine maintenance.

The circulator pumps are of a type previously used for this application. They are equipped with a vertical shaft motor which is completely sealed and mounted in the oil circulation system so that both stator and rotor windings are submerged and bearings continually lubricated at all times by the transformer oil itself. Consideration has also been given to the problem of changing the pump motor and impeller assembly in the shortest possible time should that ever become necessary.

Conclusions

The development of Hipersil has opened up many new avenues for the design of transformers. As shown here, its use, coupled with other design ideas, has made possible production of large units more economically through reduction in size and amount of material required. Weights and dimensions become particularly important in very large units. Using standard magnetic steel these have had to be shipped in nitrogen gas in special containers to get by bridge and tunnel clearances. Upon arrival they required a considerable amount of erection work and expense prior to being placed in service. The use of Hipersil automatically extends the rating size before this becomes necessary. It is apparent, too, that the same development will make possible the extending of the practical size of the portable transformer whether on car or trailer. Finally, the authors believe that this development is but another proof of the vitality of the electric power art and of the ability of modern technology to move rapidly forward even in a well developed field.

The Measurement of Body Currents

ROBERT S. SCHWAB
NONMEMBER AIEE

IN these days of supersensitive amplifiers and recording apparatus, it is very tempting to define life and death in terms of electrical activity. Whether or not this concept is accurate, we can, on present knowledge liken living tissue to a B-battery and dead tissue to a burned out generator. The function of living tissue, however, is so closely allied with its electrical activity that knowledge of the latter has given us better understanding of the working of the human body.

Great names in electrical engineering contributed to our knowledge of the physiology of tissues. Galvani in 1780 made the really startling observation that the muscle of a frog's leg could be made to contract when stimulated with the voltage from the crude Voltaic pile. That the muscle itself, on contracting, gave off a charge of its own was shown in 1870 by D'Arsonval, who noted the deflection of the needle when the muscle contracted across the poles of his galvanometer.

With improvements and greater sensitivity in recording instruments, electrical waves were obtained from the human heart (Waller, 1885; Einthoven, 1903) and from the nerve and muscle (Lucus, 1906; and Piper). In 1929 Hans Berger, with string galvanometer and amplifiers, picked up the first electrical waves from the human brain with electrodes on the scalp.

The first type of body currents to be discussed here is the rather static, direct current potential difference. It is this ever-present E.M.F., found in all living matter, small (few millionths of a volt), but constant as to polarity and relatively unchanging in time or species, that brings up the easy analogy of life to the B-battery. The living cell shows a tiny potential difference between its surface and the centrally located nucleus (Freeman). In plants, we can find a few microvolts of D.C. potential and in one animal, the electric eel, we may find as much as 500 volts. There is strong evidence that these potentials are due to different metabolic rates or energy levels in different parts of the same structure. Thus the relatively inactive, transparent membrane covering the human eye-ball (cornea) is nearly a millivolt different from the highly active, photo-sensitive retina at the back of the eye.

Nearly anywhere in the body, such potential differences may be found and in some cases might be clinically useful. For example, if an electrode is placed in the vagina, and another on the surface of the skin of the abdomen, a sudden increase in the base-line voltage difference is said to indicate that ovulation is occurring in the underlying ovary. These D.C. potentials are always associated with the first and most important character of life, namely: absorbing energy, growth, and change in structure. We call these activities metabolism and catabolism. They are found, for example, in the rose from seed to death, although the flower never moves in the sense that animals swim, fly, walk, etc. The more active part metabolically speaking is negative to the less active part. Thus the former is essentially the −; zinc, or cathode of a battery and the less active tissue the +; carbon, or anode pole.

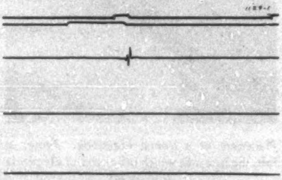

Figure 1. **Electrical response of human biceps muscle to tap on tendon**

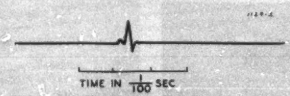

Figure 2. **Action potential in a nerve fiber (from Gasser)**

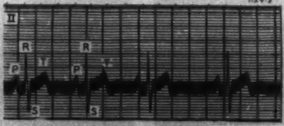

Figure 3. **Action potentials of human heart (electrocardiogram—from P. D. White)**

The second type of body currents is that associated only with the animal kingdom—the electrical activity of locomotion. It is nature's second and perhaps most interesting attribute of life, and is different from any of the D.C. potentials previously described. Contractile tissue is nature's first intrinsic movement in an environment of physical forces all in motion, such as wind, tides, rivers, etc. This tissue, when left alone "lives," i.e., has its D.C. potentials. But, when it is stimulated from without or from within, an astonishing change takes place. It moves actively, withdraws, strikes out. Associated with this defensive or aggressive movement there is an alternating current wave, a diphasic spike, which is lacking in the motionless tissues. An example of such tissue is a muscle fibre. When it is stimulated, it contracts, and a diphasic spike or group of such spikes occurs. This contractile tissue is primitive and found in all organisms that move, and is characterized by no electrical activity when quiet and by burst of such activity when stimulated to action (figure 1).

A similar structure, but more complicated, is nerve tissue. Primarily used to conduct stimuli to the contractile tissue, it acts like muscle in that it has no activity electrically when at rest, but when at work shows the same characteristic diphasic spike. Motion, as an inherent ability, however is not present in nerve tissue. (Figure 2.) In this tissue

Paper 41-129, recommended by the AIEE committee on communication, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 25, 1941; made available for preprinting May 14, 1941.

ROBERT S. SCHWAB is associated with the brain wave laboratory of the Massachusetts General Hospital and the Harvard Medical School, Boston, Mass.

very rapid shifts of metabolic activity occur. For example, A, B, and C are points in line in such a piece of living matter. When at rest they are absorbing energy (being nourished, living) and are negative to their enveloping and supporting structures. Points A, B, and C are in, let us say, contractile tissue or nerve and have a much higher metabolic rate and complexity as far as molecular structure than the simple covering membrane. Hence they are all negative to it. If point A is stimulated its energy is released by a rapid chemical change and A loses its negative electrical charge. This in turn discharges or stimulates point B etc. These rapid changes produce the diphasic wave seen in muscle and nerve potentials. It is to be noted that in 3–4 thousandths of a second the whole process is completed. This nerve conduction proceeds not like electrons in a wire, but slowly as each adjacent point goes through a chemical breakdown and stimulates the next one. The rate of conduction of such an impulse is as far as 100 meters per second in man, but is much slower in lower animals (5 meters per second in reptiles).

A third type of electrical activity is associated with the more highly developed types of contractile tissue. Cilia, tubular digestive tracts, and heart muscle have a "beat" of their own and depend no longer on outside stimuli for their continuous, regular contractions and relaxations. Every "beat" has its accompanying bursts of diphasic waves. (Figure 3.) This shows a normal electrocardiogram. Metal (silver) discs covered with flannel soaked in salt are fastened with elastic bandage to the left wrist and left foot (lead II). Wires from the two discs lead to the poles of a sensitive string galvanometer. Bromide paper moved by clock works at 5 cm. per second receives the light beam from the mirror on the string. Thus electrical changes in the heart show up optically magnified on this recording paper when it is developed. Recording from each arm or right foot and left arm are some of the other leads (I and III). A vast and important field of clinical diagnosis has been developed in the interpretation of these EKG's as they are called. They indicate pathological changes in heart muscle, disturbances in rate, rhythm, and in circulation of blood in the heart muscle itself. No complete examination of the heart can be done without such a measurement. Every hospital now has one and many doctors have them at their disposal. In 1910 they were a curiosity in this continent.

The fourth type of body electrical currents is that associated with the complex tissue that makes up the central nervous system of animals. Here, as the function is continuous during life, the ganglia and brain cell tissues are ever-active electrically and show no periods of rest in the manner of muscle and nerve. (Figure 4.) Each brain cell does not actually beat alone, but by a system of interconnections keep each other stimulated to activity. These "chains" of neurones make up the bulk of the brain and spinal cord of man and animals. According to Herrick, in man, for example there are over $10^{2,783,000}$ possible neuronal combinations—a number far greater than the total sum of all atoms in the entire solar system 10^{76}.

It is this last form of living matter, the cells of the central nervous system that interests most physiologists today. In clinical medicine, the importance of the electrocardiogram in studying the function of the heart is completely established. The newer electroencephalogram or recording of the electrical activity of the

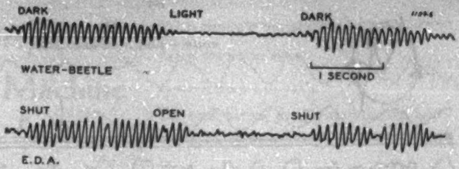

Figure 6. Comparison of the alpha rhythm in the beetle and human (from Adrian)

brain is rapidly becoming just as invaluable in the study of diseases and dysfunctions of the central nervous system. The recording of these brain waves, as the electroencephalograms are called, requires a much more sensitive type of apparatus. The heart currents obtained with surface electrodes on two of the extremities, as previously described, may reach nearly a millivolt and can be recorded directly by a string galvanometer. The brain currents picked up from small (5 mm.) lead discs attached to the scalp by electrode paste and collodion (needles or cutting the hair are not necessary) are only $^{1}/_{20\text{th}}$ of the heart's and require vacuum tube amplification before recording (see figure 4*A*, *B*). Albert Grass of Harvard and Dr. Alfred Loomis of Tuxedo Park both have developed rugged efficient battery and power-operated, push-pull amplifiers that operate ink-writing oscillographs. Offner of Chicago, Garceau of Holliston, Mass., and Rhem of New York, are other engineers who have apparatus in this field. By these brain wave machines the EEG, as the records are called, appear immediately as an ink line on the paper strip. The usual speed of the paper is 3 cm. per second and there are anywhere from 3 to 6 separate "channels" recording simultaneously. Normal human brain waves consist of two sorts. Alpha or 10 per second waves have voltages of 30 to 75 microvolts, are extremely regular, and when dominating the record are associated with easy-going stolid, reliable types (alpha type). The second type of normal activity is beta waves, 20–24 per second of voltages from 10 to 40 microvolts. They are often associated in general with tense, rather high strung people. There are so many exceptions and mixed types that the brain wave pattern is not a real index of personality, intelligence, or state of mind.

(Figure 5.) This shows a brain wave and a heart wave compared. Here is seen the regularity of the 10 per second alpha waves, their continual appearance and the smallness of the voltage as differing from the regularity, discreteness, and high voltage of the heart activity.

(Figure 6.) This shows the phenomenon of the disappearance of the alpha waves when light enters the eye. Professor Adrian of Cambridge University kindly lent me this slide. The lower tracing is from the brain of the famous Nobel Prize winner, the upper from his lowly compatriot, the English Water Beetle. Brain cells, wherever gathered together, act electrically much the same.

(Figure 7.) This shows what the human brain waves are like during sleep. Irregularity and increased voltage are characteristic. Response of the individual to outside stimulus is greatly prolonged. Here the reaction time was over five seconds. (Normal is $^1/_4$ of a second.) In very deep sleep, or when the individual is under anaesthesia, the rhythm becomes slower (3 per second) and the voltages increase. Such waves are called Delta waves. When the brain function is interfered with abnormal waves appear in the electroencephalogram. These seem to result from faster smaller waves being built up into some sort of synchrony. They appear as high-voltage spikes (100 to 200 microvolts) or high-voltage, slow waves (Delta waves). They are something like the sleep waves but usually of more voltage and slower. Periodic disturbances in the normal brain rhythm (cerebral dysrhythmia as it is called by Lennox) are found in patients who have epilepsy. The length and severity of the seizures (seconds to many minutes) are shown by the amount and voltage of these abnormal waves.

(Figure 8.) Record of brain waves of a person who has, clinically, a form of epilepsy. The seizures are short, lasting but a few seconds, and are often periods

of unconsciousness. Sometimes they show up as slight twitchings of various face muscles, but do not develop into a real convulsion. These lapses are accompanied by a characteristic wave pattern called *the wave-spike formation*, which is a slow delta followed by a short spike. In this case, the person did not respond to the neon light signal, but did to the extremely unusual stimulus of the sound of a tug-boat whistle. During severe attacks of this kind, many fail to respond even to such a noisy stimulus.

Blood clots and tumors of the brain also cause these high-voltage, abnormal waves. By means of triangulation and phase shifts with the multiple channel sets of apparatus accurate localization of these lesions is possible (84% accuracy in 400 verified cases at the Massachusetts General Hospital). An example of such an application of this technique is described. A 38-year old man was brought to the hospital in a coma with signs of pressure on the brain. A brain wave tracing showed a sharp, slow-wave disturbance on the left side of his head. Operation revealed a tumor. Six weeks after this growth had been removed the

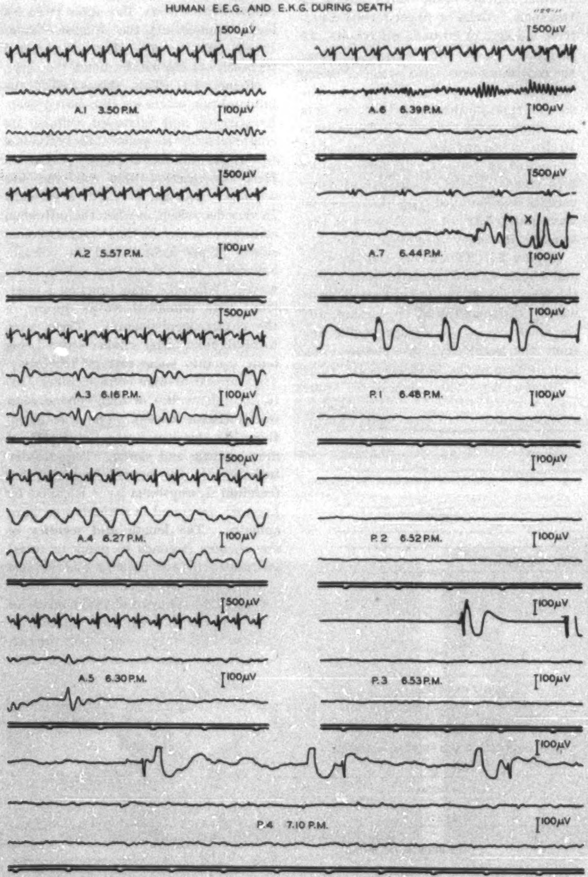

Figure 10. Brain waves and heart waves during death in a human

The electrocardiogram is top line and right and left brain waves are below. Brain waves disappear ten minutes before death. Legal death occurs at the spot marked (x) which indicates cessation of respiration and pulse. (x marks instant when intern placed stethoscope on chest to prove inaudible heart beat. The artifact produced by stethoscope touching electrode wire is shown in the tracing.) Electrocardiogram continues one minute after death, stops and then begins again. Thirty-two minutes after death heart still has three beats from pressure on chest

Damping and Synchronizing Torque of the Double-Fed Asynchronous Machine

M. M. LIWSCHITZ
MEMBER AIEE

I. Introduction

THE double-fed asynchronous machine has become important in recent times as fan drive with wide speed range. The system consists of five main machines and the fan (see figure 1). It has many springs, masses, and dampings and therefore many natural frequencies. In order to determine these frequencies, i.e. the dynamic stability of the system, the damping and synchronizing torques of all parts of the system have to be known. Some papers have been published concerning the torques of the synchronous machine. It is easy to determine torques for the D.C. machines of the system. The object of this paper is to derive formulas for the damping and synchronizing torque of the double-fed asynchronous machine. As in the case of the synchronous machine, a complicated derivation and complicated results cannot be avoided.

II. The Differential Equations of the Double-Fed Machine

In order to simplify the mathematical work a two phase machine will be considered, and the usual assumptions, i.e. no saturation and small oscillations, are made. The results will be generalized for the m_1-phase machine. The voltage equations of the two phase machine are (for the symbols see List of Symbols)

$$E_{L1}\sin\omega t = AB_I' + L_1 i_I' + r_1 i_I \quad (1)$$

$$-E_{L1}\cos\omega t = AB_{II}' + L_1 i_{II}' + r_1 i_{II} \quad (2)$$

$$E_{L2}\sin(s\omega t+\delta) = AB_d' + L_2 i_d' + r_2 i_d \quad (3)$$

$$-E_{L2}\cos(s\omega t+\delta) = AB_q' + L_2 i_q' + r_2 i_q \quad (4)$$

where

$$A = \frac{2}{\pi}\tau_p l_i \omega \times 10^{-8} \quad (5)$$

i_I, i_{II}, i_d, and i_q are the currents in the four windings. B_I, B_{II}, B_d, and B_q are the resultant inductions in the axes of the winding produced by all currents. Between the inductions consists the relation[1]

$$\begin{aligned} B_I &= B_d\cos\gamma - B_q\sin\gamma \\ B_{II} &= B_d\sin\gamma + B_q\cos\gamma \end{aligned} \quad (6)$$

where

$$\gamma = \frac{x}{\tau}\pi \quad (7)$$

is the angle between the axes of phase I of the stator and phase I of the rotor. For the inductions B_d and B_q the following equations hold

$$B_d = \frac{x_m}{A\omega}(i_d + i_I\cos\gamma + i_{II}\sin\gamma)$$

$$B_q = \frac{x_m}{A\omega}(i_q + i_{II}\cos\gamma - i_I\sin\gamma) \quad (8)$$

With two new variables

$$\begin{aligned} I_d &= i_I\cos\gamma + i_{II}\sin\gamma \\ I_q &= -i_I\sin\gamma + i_{II}\cos\gamma \end{aligned} \quad (9)$$

the total torque of the machine will be[1,2]

$$T = A\omega(B_q I_d - B_d I_q) \quad (10)$$

With

$$\gamma = \frac{x}{\tau}\pi = \omega_{rav.}t + \epsilon = \omega_{rav.}t + \epsilon_0\sin zt \quad (11)$$

and

$$\alpha = s\omega + z \quad \beta = s\omega - z \quad (12)$$

the following four simultaneous differential equations will be found after some conversions.

$$E_{L1}\left(\cos s\omega t + \frac{\epsilon_0}{2}\cos\beta t - \frac{\epsilon_0}{2}\cos\alpha t\right) = -A(B_d\beta' + B_q') - L_1(I_d\beta' + I_q') - r_1 I_q \quad (1a)$$

$$E_{L1}\left(\sin s\omega t + \frac{\epsilon_0}{2}\sin\beta t - \frac{\epsilon_0}{2}\sin\alpha t\right) = A(B_d' - B_q\beta') + L_1(I_d' - I_q\beta') + r_1 I_d \quad (2a)$$

$$E_{L2}\sin(s\omega t+\delta) = (1+\tau_2)AB_d' + \frac{A\omega}{x_m}r_2 B_d - L_2 I_d' - r_2 I_d \quad (3a)$$

$$E_{L2}\cos(s\omega t+\delta) = (1+\tau_2)AB_q' + \frac{A\omega}{x_m}r_2 B_q - L_2 I_q' - r_2 I_q \quad (4a)$$

III. The Torques

A straightforward solution of the four equations is possible. For the four variables has been found

$$B_d = -E_{L1}\frac{x_m}{A\omega}\left[(a_s\cos s\omega t - b_s\sin s\omega t) - \frac{\epsilon_0}{2}(a_{II}\cos\beta t - b_{II}\sin\beta t) - \frac{\epsilon_0}{2}(a_8\cos\alpha t - b_8\sin\alpha t)\right] \quad (13)$$

$$B_q = -E_{L1}\frac{x_m}{A\omega}\left[(a_s\sin s\omega t + b_s\cos s\omega t) - \frac{\epsilon_0}{2}(a_{II}\sin\beta t + b_{II}\cos\beta t) - \frac{\epsilon_0}{2}(a_8\sin\alpha t + b_8\cos\alpha t)\right] \quad (14)$$

Paper 41-110, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 14, 1941; made available for preprinting May 6, 1941.

---

brain wave was normal again in this area.

(Figure 9.) Abnormal, slow-wave pattern obtained from a patient unconscious due to large blood clot on the brain. Abscesses and injuries to the brain can also be localized by this method.

(Figure 10.) Changes in the electrocardiogram and electroencephalogram occurring in a patient dying from cerebral hemorrhage. Electrical activity of the brain in this case ceased before that of the heart.

(Figure 11.) Table of comparison of normal electrical pattern of muscle, heart, and brain. A normal muscle lives at the second level of no electrical activity except on stimulus. When a muscle "beats" rhythmically and continuously, it is a diseased or dying tissue. The heart lives a normal life at this level of rhythmic discharge, and is abnormal when it depends on outside stimulus. The brain exists normally in the fourth level of continuous, arhythmic and asynchronous activity.

Summary

D.C. potentials are associated with static cellular life and are a product of metabolism.

A.C. potentials are associated with many tissues controlling or responding to movement.

Brain tissue is the most highly developed and exists normally in a state of constant, irregular electrical activity.

$$I_d=-E_{L1}\left[(a_{14}\cos s\omega t-b_{14}\sin s\omega t)-\frac{\epsilon_0}{2}(a_{12}\cos\beta t-b_{12}\sin\beta t)-\frac{\epsilon_0}{2}(a_{13}\cos\alpha t-b_{13}\sin\alpha t)\right]\quad(15)$$

$$I_q=-E_{L1}\left[(a_{14}\sin s\omega t+b_{14}\cos s\omega t)-\frac{\epsilon_0}{2}(a_{12}\sin\beta t+b_{12}\cos\beta t)-\frac{\epsilon_0}{2}(a_{13}\sin\alpha t+b_{13}\cos\alpha t)\right]\quad(16)$$

$$b_{13}=a_8\lambda_2+b_8\lambda_1$$

$$b_{14}=(a_3\nu_2+b_3\nu_1)-K\frac{r_2\cos\delta+sx_2\sin\delta}{r_2^2+(sx_2)^2}$$

From equations 10, and 13 to 16 the torques of a m_1-phase machine are

Constant torque

$$T_c=m_1E_{L1}^2x_m(a_3b_{14}-b_3a_{14})\text{ watts}\quad(17)$$

Damping torque

$$T_d=m_1E_{L1}^2x_m\frac{1}{2z}[a_3(b_{12}+b_{13})-b_3(a_{12}+a_{13})+b_{14}(a_8+a_{11})-a_{14}(b_8+b_{11})]\text{ watt-sec}\quad(18)$$

Synchronizing torque

$$T_s=m_1E_{L1}^2x_m\frac{1}{2}[a_3(a_{12}-a_{13})+b_3(b_{12}-b_{13})+a_{14}(a_8-a_{11})+b_{14}(b_8-b_{11})]\text{ watts}\quad(19)$$

A simple expression for the constant torque has been given in a previous paper.[3]

While the torques of the synchronous machine depend on the angle δ and the excitation, the torques of the double-fed asynchronous machine depend on the angle δ, the secondary voltage, and the slip.

The derivations made above are valid when the synchronous machine (machine 2, figure 1) is larger than the asynchronous machine, for example, when two or more asynchronous machines are connected in parallel to a single synchronous machine and the oscillation of one of the asynchronous machines is considered. In this case the secondary voltage can be assumed independent of the oscillation and proportional to the average slip (equations 3*a* and 4*a*). When the synchronous machine is of the same size as the asynchronous machine the change of the slip has to be taken into acount in the equations 3*a* and 4*a*. The results in this case become much more complicated than in the case considered.

Relative Accuracy of Three-Phase Metering Combinations

C. T. WELLER
MEMBER AIEE

Synopsis: This paper grades several three-phase combinations of instrument transformers and watthour meters under various conditions according to their approach to the best standard practice. The combinations are described and sources of uncertainty or of error are discussed. Diagrams are included to show the schematic connections of the component transformers and meters, both separately and in combination and of the power systems to be metered.

Introduction

FROM time to time questions arise in regard to the accuracy of three-phase metering combinations of instrument transformers and watthour meters. A definite estimate of the accuracy to be expected can usually be made for a given installation if sufficient details are available. However, in many cases all that is required is an idea of the relative accuracy obtainable. To meet such situations, relative accuracy under various conditions is here assigned to typical metering combinations now in use and to others sometimes proposed. These combinations are considered principally from the instrument-transformer standpoint. Operating and metering difficulties sometimes encountered with Y-connected potential transformers and the effects of various secondary interconnections on the metering accuracy are discussed. Much of this discussion applies to three-phase indicating wattmeters as well as to watthour meters.

A summary of the paper is given in table I, wherein the relative accuracy is graded from A to E. Grade A is assigned to cases where the metering combination and the conditions of application represent the best standard practice, which ordinarily embodies a close approach to the ideal. Three of the four power systems included are classified as three-phase, three-wire. There are five instrument transformer combinations and three types of watthour meters: 2-element, 2½-element, and 3-element, respectively. In each case, sufficient comments are included to make table I reasonably self-explanatory. Table I is supplemented by figures 1 to 4, which show the schematic connections of the different parts and also of six complete metering applications.

It should be kept in mind that the ideal polyphase metering combination from the standpoint of accuracy is one that can be resolved into two or more component single-phase sections. Each section consists of one potential transformer, one current transformer, and one meter element. The instrument transformers can be checked for accuracy at any time and a portable single-phase indicating wattmeter or a watthour-meter standard can be added to the secondary meter circuits. Thus the accuracy of the polyphase combination can be verified to the satisfaction of any legal authority from the summation of two or more sets of single-phase results obtained simultaneously. For the highest accuracy, complete single-phase sections should be used as standards entirely separate from the polyphase combination. However, the accuracy obtainable with either method will not be uniform over wide ranges of power factor or load.

Power Systems

Three-Phase Three-Wire Systems

These systems may be classified according to the treatment of the system neutral. Systems with isolated neutral (figure 1*a*) or with a ground at one neutral point only (figure 1*b*) are common and require no special comments. Ordinarily it is immaterial from the metering standpoint whether the neutral is isolated or is grounded at one point either solidly or through low or high impedance; a ground-fault neutralizer (Petersen coil) constitutes an example of a high-impedance ground. Separate classifications for the two systems are justified, since single-phase loads could be connected between any line and ground with single-grounded neutral systems, particularly if the neutral is grounded through a low impedance, whereas such loading is not possible with isolated-neutral systems. For systems grounded at but one neutral point, it is assumed that there will be no line-to-ground loads.

Systems grounded at more than one neutral point (multiple grounds—figure 1*c*) in the manner shown probably should be considered as three-phase, four-wire systems, even if not so classified, not only because single-phase loads could be connected between any line and ground as just pointed out, but particularly because such loads can now be applied through the Y-Y-connected power transformers. These transformers often are provided with tertiary windings for closed-delta connection to take care of the triple harmonics in the exciting currents.

Three-Phase, Four-Wire Systems

This classification applies to systems having four metallic conductors (figure 1*d*). Such systems also are common and usually supply single-phase loads connected between any line and the neutral in addition to three-phase, three- or four-wire loads. The system neutral may or may not be grounded at one or more points.

Instrument Transformers

The principal functions of instrument transformers are to insulate low-voltage

Paper 41-125, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 16, 1941; made available for preprinting May 14, 1941.

C. T. Weller is an electrical engineer in the general engineering laboratory of the General Electric Company, Schenectady, N. Y.

1. For all numbered references, see list at end of paper.

measurement devices from dangerous-to-life line voltages and to act as multipliers for them. In the instrument transformer combinations under consideration (figure 2), the current-transformer primaries are connected in the proper lines and their individual secondaries supply individual meter-current circuits. On the other hand, the potential-transformer primaries are connected either line-to-line or line-to-neutral, so their individual secondaries either supply individual meter potential circuits or constitute part of a network.

The currents and voltages obtained from the secondaries of instrument transformers usually represent the corresponding primary quantities with acceptable accuracy without making corrections for the respective ratio and phase angle errors, but such corrections for either the actual or the "average" characteristics frequently can be applied when necessary. Several exceptions to these statements are discussed under "Metering Considerations" but some of a more general nature are mentioned here. Thus for the case of three potential transformers connected closed-delta-delta, the normal unit characteristics may be considerably altered because of a fairly large circulating current in the windings resulting from small differences between the units. However, line-to-line connected potential transformers are, in general, much freer from various disabilities than Y-connected potential transformers.

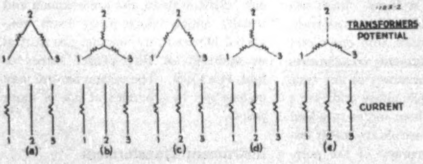

Figure 2. Instrument - transformer combinations for three-phase systems

(a), (b), (c), (d) For three-phase, three-wire systems; *(d), (e)* for three-phase, four-wire systems

For the latter, the three line-to-neutral voltages with isolated primary neutral may contain appreciable triple harmonics due to the suppression of such harmonics in the respective exciting currents; this distortion actually may cause an erroneous voltage indication, to say nothing about rendering normal transformer corrections of doubtful value. If the primary neutral is grounded, but if the system neutral is ungrounded either permanently or temporarily, the potential transformer line-to-neutral voltages may become very badly distorted and the neutral point, in effect, may even get outside of the supply-voltage triangle due to switching surges.[1,2,3]

Watt-Hour Meters

Two-Element Meters (Figure 3*a*)

These meters have two separate driving elements, which may act either on separate disks mounted on a common shaft or on different segments of the same disk. Such meters are standard for three-phase, three-wire systems.

Two-and-One-Half-Element Meters (Figure 3*b*)

These meters also have two separate elements but each set of current coils is divided into two equal, separate sections. One section and the corresponding potential coil of one element are supplied from one system phase and the other similarly arranged element is supplied from a second system phase somewhat like a straight 2-element meter. Current from the third system phase flows in a reversed direction through the two extra meter current-coil sections in series and thus reacts with the voltages of the other two system phases applied to the two meter potential coils. The vector sum of these two phase voltages usually equals the voltage of the third phase, so it is evident that the "$^{1}/_{2}$-element" then operates correctly but with a synthetic instead of an actual third-phase voltage. However, this vector sum does not always correctly represent the third-phase voltage and under such conditions the "$^{1}/_{2}$-element" registration will be in error; of course, it contributes but one-third the torque and its error but one-third the effect in a balanced system.

These meters also are known as 2-element meters with split current coils. They are standard for three-phase, four-wire systems when the three voltages are approximately balanced and are used to avoid the extra potential transformer, wiring, and expense required for a 3-element meter.

Three-Element Meters (Figure 3*c*)

These meters have three separate elements which are supplied from the three phases of a three-phase, four-wire system for which they are standard under all conditions of load and of voltage balance. The meters are entirely satisfactory for three-phase, three-wire systems having one or more neutral grounds.

Metering Considerations

Single-Phase Metering

The metering of a single-phase system will serve as an introduction to the metering of polyphase systems. A single-phase system requires one potential transformer, one current transformer, and one watthour meter. Certificates for the two instrument transformers will give the respective ratio correction factors to within 0.1 per cent and the phase angles to within three minutes. The watthour meter can be adjusted to be correct within say 0.3 per cent over a medium load range. Thus an overall accuracy within 0.5 per cent over such a load range near unity power-factor could be expected, even if the errors were all in the same direction, which would be most unusual. Better accuracy can be obtained at a definite and fairly steady load point by taking the average of a large number of observations on a high-grade portable indicating wattmeter, which can be checked to within 0.15 per cent over the upper part of its scale. On a similar basis, an overall accuracy within 0.35 per cent could be expected under this condition.

The single-phase metering combination just described represents the simplest case, where the corrections determined for the individual parts can readily be combined algebraically and an estimate made of the best accuracy obtainable. Since a polyphase power system consists in effect, of two or more out-of-phase single-phase systems, it should be obvious that the highest accuracy can be obtained only if single-phase metering conditions are maintained. This accounts for long-standing cautions against some "secondary interconnections" in polyphase metering circuits.

Three-Phase Three-Wire Metering

Applying this idea to a three-phase, three-wire, ungrounded system, two current and two potential transformers and two single-phase watthour meters would

*Figure 1*a*.

**Figure 1*b*—it is assumed that there will be no line-to-ground loads.

***Multiple grounds—figure 1*c*—these 3-phase, 3-wire systems probably should be considered as 3-phase, 4-wire systems and provision made for metering correctly single-phase loads connected between any line and neutral or ground.

†In *cases 16* and *17*, the potential-transformer and system neutrals are tied together; the system neutral may either be isolated from ground (figure 1*d*) or grounded at one or more points. See text for further comments on the 2½-element metering combination.

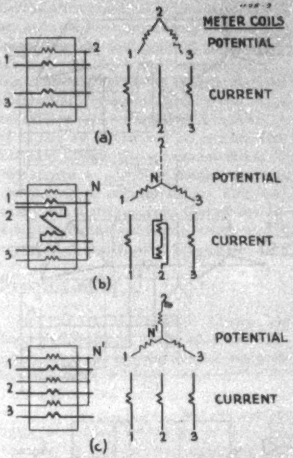

Figure 3. Polyphase watt-hour meters

(a) Two-element for three-phase three-wire systems

(b) Two-and-one-half-element for three-phase four-wire systems

(c) Three-element for three-phase three- or four-wire systems

be required and these would constitute two separate, single-phase metering circuits. Of course, such separate metering circuits are quite unusual, except for special tests. The meters are slightly handicapped by the fact that a phase displacement of 30 degrees exists between the line-to-line voltages and the line currents (at unity power factor).

Thus for *case 1* in table I (figure 4*a*), the first "secondary interconnection" occurs in the substitution of a 2-element polyphase watthour meter for the two single-phase meters, which necessitates an average correction for the instrument-transformer and meter-element errors. Other interconnections occur in the substitution of three secondary leads for four both for the current transformers and for the potential transformers. This tends to complicate the ratio and phase-angle tests, particularly if the secondary leads are long.

For balanced systems, the secondary current in the common lead will equal those in the other two leads, but will be 120 degrees out of phase with them and the resulting additional common burden for the two current transformers must be allowed for in making up the respective test burdens. If this common burden is large due to a long lead or to measurement or protective devices connected in series therewith, it will be necessary to know the phase sequence of the power system, as well as the actual phases in which the current transformers are connected in order to test them properly.

For two equal potential-transformer burdens, the current in the common potential lead will be $\sqrt{3}$ times those in the other two leads and 30 degrees out of phase with them; neglecting the voltage drop in the leads may cause appreciable errors in the ratio and phase-angle results. Further complications occur if a burden is connected across the open delta (third phase without potential transformer); even if its power factor is unity, it imposes its full voltamperes at 0.5 power factor on both potential transformers, leading in one case and lagging in the other, thus again making it necessary to know the phase-sequence of the power system and the connections of the individual transformers thereto: the importance of this proceeding increases with the magnitude of the burden. Somewhat similar considerations apply when double autotransformers are used to shift the phase of the potential transformer voltages to supply var- or voltampere-hour meters, since the net effect is to change the burden distribution. Interconnected, low-power-factor burdens sometimes have surprising effects: when two potential transformers supply such Y-connected burdens, not only does one transformer supply all the energy necessary, but it also tends to excite the other transformer secondary winding! This undesirable effect increases with the magnitude of the burdens and may be overcome by adding suitable non-inductive burdens.

In spite of the various uncertainties just outlined, some of which are inherent in the *case 1* metering combination, satisfactory accuracy is usually obtained. A similar statement applies when the power-system neutral is grounded at one point only as in *case 2*.* Thus the highest relative accuracy—grade A—is assigned to *cases 1* and *2*.

A much greater degree of uncertainty exists when three Y-connected potential

---

**Case 3* and others involving grounds at more than one power-system neutral point are discussed under "Three-Phase, Four-Wire Metering."

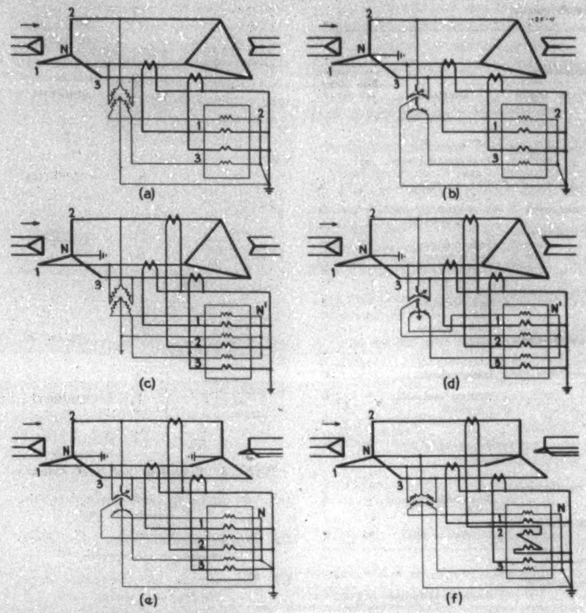

Figure 4. Schematic connections of three-phase metering combinations (cases outlined in table I)

- (a) *Case 1* (figures 1*a*, 2*a*, 3*a*)
- (b) *Case 5* (figures 1*b*, 2*b*, 3*a*)
- (c) *Case 8* (figures 1*b*, 2*c*, 3*c*)
- (d) *Case 11* (figures 1*b*, 2*d*, 3*c*)
- (e) *Case 15* (figures 1*c*, 2*d*, 3*c*)
- (f) *Case 17* (figures 1*d*, 2*e*, 3*b*)

transformers are substituted for two connected open delta to supply the two potential circuits of a 2-element meter as in *cases 4* and *5* (figure 4*b*). Here it is impossible not only to allocate properly the three individual potential transformer corrections, which may differ slightly, but also to resolve the combination into component single-phase metering circuits, which is much more important. The three line-to-neutral transformer voltages will be distorted (peaked) if the primary neutral is isolated and may be distorted if it is grounded with system neutral isolated, as was pointed out under "Instrument Transformers." However, the secondary line-to-line voltages applied to the two meter circuits will not be distorted, assuming sine-wave supply voltages. The uncertainty necessitates assigning a considerably lower relative accuracy—grade C—to *cases 4* and *5*.

A similar indeterminate situation exists when two open-delta connected potential transformers are used to supply the three Y-connected potential circuits of a 3-element meter as in *cases 7* and *8* (figure 4*c*), which is sometimes recommended for low-power-factor loads on three-phase, three-wire systems. Here the three line-to-neutral meter voltages are somewhat distorted due to the suppression of the triple harmonics in the exciting currents. Such distortion will not occur if the inductive meter circuits are replaced by noninductive wattmeters.

The foregoing situation is not improved by the substitution of three Y-connected potential transformers for the two in open delta, if the two secondary neutral points are not connected as in *cases 10* and *11* (figure 4*d*). Here again as in *cases 4* and *5*, the three line-to-neutral transformer voltages will be distorted if the primary neutral is isolated and may be distorted if it is grounded with system neutral isolated, but the secondary line-to-line voltages applied to the Y-connected meter circuits will not be distorted with a sine-wave supply.

The indeterminate features of *cases 10 and 11* are partly overcome by connecting the potential-transformer-secondary and meter-potential-circuit neutral points as in *case 13*. However, the three line-to-neutral voltages may be distorted and potential-transformer-neutral instability may result as with similar neutral conditions in *cases 4* and *10*, due to the attempt to ground the power system through the potential transformers. Because of this, *case 13* is assigned relative-accuracy grade C also.

Grounding the power-system neutral at one point as in *case 14* translates *case 13* into standard practice. *Case 14* closely approaches the ideal of component single-phase metering sections mentioned in the "Introduction." The eight secondary leads (as in figure 4*e*) are practically equivalent to twelve, since the currents in the two common leads normally are negligible. Three single-phase watt-hour meters may readily be added for verification purposes and each meter or meter element operates at the same power factor as that of the load in its respective phase, which is particularly advantageous at low power factors. This favorable condition does not exist with balanced three-phase loads in *cases 1* and *2;* however, these are entitled to share relative-accuracy grade A with *case 14* for most applications.

THREE-PHASE FOUR-WIRE METERING

A 3-element meter with three current and three potential transformers as in *cases 14, 15* (figure 4*e*) and *16* is standard both for three-phase, three-wire systems with at least one neutral point grounded and for three-phase, four-wire systems. Relative-accuracy grade A is assigned to this metering combination. Three-phase, three-wire systems with multiple neutral grounds are equivalent in many respects to three-phase, four-wire systems, even if not so operated with single-phase loads connected between any line and the neutral ground.

A $2^{1}/_{2}$-element meter with three current and two potential transformers as in *case 17* (figure 4*f*) is standard for the usual condition where the three line-to-neutral voltages of the three-phase, four-wire system are fairly well balanced; relative-accuracy grade B is assigned to this metering combination.

Although designed primarily for three-phase, four-wire systems, it should be evident from a consideration of *cases 16* and *17* that the $2^{1}/_{2}$-element metering combination can be substituted for the 3-element metering combination in *cases 14* and *15*. Relative-accuracy grade B would then be assigned unless the system-neutral grounds are effected by means of ground-fault neutralizers; the line-to-neutral voltages may then be consider-

Impulse Strength as a Measure of Cable Quality

L. I. KOMIVES
ASSOCIATE AIEE

Synopsis: Testing cables by means of the impulse generator, originally developed for use in studying the effect of lightning on cables, is becoming recognized more and more as a useful method for determining cable quality. It is felt that the amount of data accumulated during the past ten years is sufficiently large to be used in formulating a theory concerning the factors governing the impulse strength of cables. It is indicated in this paper that maximum rather than average stress should be taken into account when impulse test results are evaluated, since the maximum stress at breakdown is a measure of the quality of the insulation alone. This view is contrary to that generally accepted in this country although some workers in this field abroad have accepted this theory for some time.

Introduction

THE Detroit Edison Company has in the past sponsored a number of tests to determine the impulse strength of various types of cable in relation to other electrical equipment. Results of some of these tests on "solid-type" impregnated paper (24 and 4.8 kv) and varnished cambric (4.8 kv) cables were published by McCabe[1,2] from time to time. About two years ago the scope of these tests was enlarged to include various types of impregnated paper insulated cables proposed for extra-high voltage service as no impulse test data were then available on such cables. Held and Leichsenring[3] and Foust and Scott[4] have since published results of impulse tests on oilfilled cables.

Oilfilled, oilostatic, compression, and gas-filled (Beaver) cables were in commercial use two years ago at voltages above those recommended for solid type cables. As gas-filled cable was not on hand, oilfilled, oilostatic, and compression cables having equal insulation thicknesses, were tested. The results of these tests indicated that maximum rather than average stress determines the impulse strength of the cable. In order to verify this statement, tests were made on solid type cables of various conductor diameters, conductor surfaces and insulation thicknesses, and on low gas pressure cables. In computing average stresses at breakdown on the solid type cables, no definite correlation could be established between these data and the quality of the insulation as observed by examination of the samples. On the other hand, when maximum stresses at breakdown were computed, values were obtained that showed pronounced increase with improving insulation, reaching a constant maximum value at the best obtainable impregnation. Further tests on oilfilled cables showed that uniformity of taping as determined by the Mildner diagram affects the maximum stress at breakdown in a similar manner as does the degree of impregnation. This correlation is a strong indication of the significance of the maximum stress as the criterion of quantitative breakdown.

Previous Work

No universally accepted theory has been proposed that would allow the computation of the impulse breakdown voltage of a cable of known construction details and known insulation qualities. A study of the published data on impulse tests of cables, however, permits the drawing of conclusions concerning certain factors that influence the impulse strength.

Paper 41-131, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 8, 1941; made available for preprinting May 14, 1941.

L. I. Komives is with The Detroit Edison Company Detroit, Mich.

The author wishes to extend his thanks to A. Gemant, F. M. Hull, and J. Sticher of The Detroit Edison Company for their collaboration and constructive criticism.

1. For all numbered references, see list at end of paper.

---

ably unbalanced due to unequal capacitances to ground of the three line conductors. Under this condition, the 3-element metering combination should be used. Of course, the straight 2-element metering combination (*case 2*) may be used for all such three-phase, three-wire systems if the single-phase loads to neutral are negligible or if these loads are balanced.

The limitations just placed on the application of 2-element metering combinations are important. In *cases 3* and *6*, for example, a load connected between the line without current transformer and ground would not be metered at all and the meter voltages would not have the proper magnitude or phase for loads connected between the other two lines and ground; this accounts for the low relative-accuracy grades D and E, respectively. The grade C accuracy assigned to the 3-element metering combination in *cases 9* and *12* is due to its being indeterminate and not to the possibility of incorrectly metering single-phase loads to ground.

In the foregoing discussion, the term "indeterminate" has been used to describe conditions where it is impossible to resolve the metering combination into component single-phase sections and thus to allocate instrument-transformer and meter corrections definitely. Although it need not be assumed that "indeterminate" is synonymous with "inaccurate," arguments advanced as to the correctness of such a metering combination may sound unconvincing. It should be emphasized that all important metering installations are at all times subject to verification or checking when questions arise in regard to their correctness.

Conclusions

A general idea of the performance to be expected from several three-phase metering combinations under various conditions is conveyed by the relative accuracy assigned thereto in table I. Among the many cases included, it should be possible to find examples approximating other cases sometimes used or proposed and thus permit grading them also. From the accompanying discussion, it should be evident that in cases where grade A is assigned to the metering combination, very satisfactory accuracy can be obtained if appropriate secondary connections are used and if the instrument-transformer corrections are properly applied.

(a). QUALITY OF INSULATION

Held and Leichsenring[3] and Busse and Vogel[5] established that the use of denser papers results in higher impulse strength; and that temperature of the cable during the tests, provided the limits do not exceed those of commercial operation, does not measurably influence the impulse strength.[3] By inference, the latter signifies that the viscosity of the impregnating compound (which decreases as the temperature increases) has also a very limited effect on the impulse strength. Whether "straight" mineral oil is used to impregnate the cable or a mixture of mineral oil and rosin, appears to have no effect on the impulse strength of the cable. The degree of impregnation at a given temperature, however, seems to have a very decided effect.[1] That service aging of solid-type cables, which generally results in a decrease of the degree of impregnation, will also result in a proportional decrease of impulse strength is indicated[2] but this requires further study.

(b). GEOMETRY OF CABLE AND SURFACE OF CONDUCTOR

The effect of conductor diameter (minimum radius) and conductor surface appears to have influenced the results of several workers. For instance when specially constructed copper conductors having the same diameter and smooth outer surface were used, the number of variables was reduced to such an extent that from the results obtained it was possible to disprove the theory still generally accepted in this country, that thinner insulation possesses a comparatively higher impulse strength.[3] Tests on cables with sector shaped conductors disclosed the fact that 80 per cent of the failures were on the "shoulder" (minimum radius of the conductor) of the sector.[1] The same author reports that strand-shielding improves the impulse strength considerably.[2] Davis and Eddy found that the impulse strength of rubber in sheet form is approximately 50 percent higher than that of rubber cable insulation of the same wall thickness.[6]

(c). POLARITY OF THE IMPULSE WAVE

Schneeberger,[7] in discussing the effect of polarity of the impulse wave on the impulse strength of a cable, indicated that when a positive wave was used, the breakdown value was 20 percent lower than with a negative wave. Later reports contradict this finding. One author has found no difference in oilfilled cables but in solid cables the impulse strength, using a negative wave, was from 5 to 13 percent lower than when a positive wave was used.[3] Another paper states that the authors found no difference in impulse strength due to variations in the shape and polarity of the impulse wave.[6]

Figure 1. Impulse terminal assembly for high-voltage surge test

In view of the above data, no definite conclusion can be drawn in regard to the effect of the polarity of the impulse wave on the impulse strength of the cable. For this reason, small variations in absolute values reported by various authors may exist, but the relative rating of the individual samples will probably still remain the same.

Method of Test and Testing Equipment

Engineers of The Detroit Edison Company favor the impulse testing of electrical apparatus with a negative wave because field testing has shown the prevalence and greater importance of negative lightning strokes in connection with transmission line outages. A method of testing with sufficiently high potential surge to obtain breakdown with one surge is also favored for reasons of simulating conditions in the field. All tests described in this paper, therefore, were made with negative wave and attempts were made to obtain breakdown with one surge.

The impulse generator used has been previously described.[1] For these tests additional condensers were used in series and both ends of the cable were encased in terminals built to withstand 1,000 kv and

200 psi pressure. Figure 1 shows the terminal assembly. Figure 2 shows the method used in connecting the cable to the impulse generator. Figure 3 is an oscillogram of the incident wave (approximately 0.05×24 microsecond) with the cable disconnected, and figure 4 is a typical wave recorded during breakdown of sample *J*1. It should be noted that the steepness of the wave front is somewhat lessened when the cable is connected to the generator.

Presentation of Results and Description of Samples

The results of the impulse tests which form the basis of this paper, are graphically illustrated in figure 5, and complete data are supplied in tables I and II.

R. Minimum radius over insulation.

n. Number of strands in outer layer.

This chart was compiled to show breakdown voltage and maximum stress at breakdown, for all the samples tested in Detroit as well as those tested elsewhere, when sufficient data were available. It should be noted that the Detroit samples are designated by a letter and a number, each letter representing a cable and each number an individual measurement on a sample of the cable. The data published by Foust and Scott,[4] is represented by the same numbers the authors used in their paper. Number 34 refers to the paper cable sample used by Davis and Eddy[6] and numbers 35 to 40 represent the Held and Leichsenring samples.[8] It should be noted that this latter group represents minimum values of groups of measurements.

Pertinent information regarding the Detroit samples is given in the following:

Samples *A*1, *A*2, *I*1, and *J*1 were solid type, single-conductor cables. The *A* samples had a small conductor and thin insulation. Sample *I*1 had a conductor diameter similar to that of samples *E*1 to *E*4 (compression and oilostatic) but an insulation thickness almost twice as great (170%). Sample *J*1 had a large conductor diameter similar to that of samples *F*1, *F*2, *G*1, *G*2, *H*1, and *H*2 (oilfilled) but greater insulation thickness (130 and 111% respectively).

Samples *B*1, *B*2, *B*3, *B*4, *B*5, and *B*6 were low gas pressure, three-conductor, sector, shielded, 27.6-kv cables. Samples *B*1, *B*2, and *B*3 represent three conductors of one section and samples *B*4, *B*5, and *B*6 the three conductors of another section of the same cable. Ten complete failures were observed in the six samples, seven of which were at the "shoulders" of the sector.

Samples *C*1, *C*2, *C*3, *D*1, *D*2, and *D*3 were solid type, three-conductor, sector, shielded, 24-kv cables. The *C* samples represent the three conductors of one cable, while the *D* samples are the three conductors of another cable. The two cables were identical except for the strand-shielding with semi-conducting tapes employed in the latter group. The manufacturer who made these cables used the same type of paper, same taping machine, impregnated the two cables in the same tank, and lead covered both on the same day. Therefore, except for the strand-shielding, there should be no other variables. Failures in all six samples occurred at or near the "shoulder" of the sector.

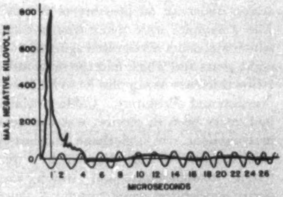

Figure 4. Typical breakdown wave

Samples *E*1, *E*2, *E*3, and *E*4 were taken from the same oval-shaped, single-conductor cable. Samples *E*1 and *E*3 were tested in a steel pipe containing nitrogen under 200 psi (compression cable). *E*2 was tested as an oilostatic cable, that is, the armoring and lead sheath were removed, and the pipe that contained the cable was filled with oil under 200 psi. *E*4 was tested without the application of pressure; in other words, as a solid type cable. All four samples failed near the major axis of the oval conductor. Figure 6 shows the Mildner-diagram of cable *E*.

Samples *F*1, *F*2, *G*1, *G*2, *H*1, and *H*2 were taken from three single-conductor oilfilled cables made by three manufactur-

ers, respectively. All six samples were tested under an oil pressure of ten psi. The *F* samples were taken from a cable which was under accelerated aging test for eight years and which had the same insulation thickness as samples *E*1 to *E*4 (compression and oilostatic). Cable *G* which had never been in service, was identical in conductor size and shape, insulation thickness, etc. to cable *H*, made by a different manufacturer and which was under accelerated aging test for a short time. Figure 8 shows the Mildner-diagram of cable *G* and figure 7 of cable *H*.

Discussion of Results

Among the 26 samples tested in Detroit, *A*1, *A*2, *I*1, and *J*1 were single conductor, solid type cables, each having a standard stranded, round, copper conductor. Since the taping and impregnation were approximately the same for the four samples, they offer a basis for comparison of geometrically different constructions. Tabulating the average stresses at breakdown discloses a ratio of 1.43 between maximum and minimum values. Calculating on the basis of maximum stresses after correcting for stranding, yields a ratio of 1.11. This is clearly an indication that maximum rather than average stresses determine the breakdown voltage.

Further indication of the correctness of this theory is obtained in considering another group of three cables of equal insulation characteristics, namely samples *E*4, *F*1, and *F*2. Both cables from which these samples were taken had the same insulation thickness, uniform taping, and high degree of impregnation, but cable *F* had a conductor diameter very much larger than that of cable *E*. The ratio of average stresses of cables *E* and *F* was 1.2 in favor of cable *F*. The ratio of maximum stresses is, on the other hand, 1.01.

Having considered two different groups of cables separately, comparison of the two groups in relation to each other will now be made. The maximum stresses of the first group vary from 2,660 to 2,980 volts per mil, whereas the corresponding values for the second group are 3,250 to 3,450 volts per mil, the averages of the two groups being 1.21. Visual examination of the samples indicated that those in the first group exhibited a lesser uniformity of taping and a lower degree of impregnation than samples in the second group. Thus it can be concluded that the maximum stress, which has been shown to be independent of the geometry of the construction, depends solely upon the quality of the insulation, as measured by the uniformity of taping and the degree of impregnation.

Further and more specific proofs of this statement are supplied by results of tests on other groups of cables. The influence of taping and that of impregnation will be considered in separate paragraphs.

The best evidence in regard to the influence of the quality of taping on the impulse strength of cables was supplied when samples *G*1, *G*2, *H*1, and *H*2 were tested and examined. The cables from which these samples were taken, were identical in dimensions and, both being oil-filled, possessed the same high degree of impregnation. The samples differed from each other in only one respect, i.e. in the degree of uniformity of taping which again was manifested in much lower maximum stress at breakdown (23 percent) for the samples with inferior taping.

The importance of the degree of impregnation without the disturbing influence of variations in taping is demonstrated when the results of tests on the low gas-pressure cable, samples *B*1 to *B*6, are examined and compared with the results of tests on a well-impregnated solid-type cable, samples *C*1 to *C*3. Both types of cables contained sector shaped conductors having nearly equal minimum radii (167 and 151 mils, respectively) at the "shoulders," "compack" stranding was employed, producing approximately equally smooth surfaces; and the taping was equally uniform. The less complete impregnation in the low gas-pressure samples, therefore, appears to be responsible for the 15 percent decrease in maximum stresses.

The smoothness of the electrode surface has for some time been known to influence the impulse flash-over values in gases and liquids. How much practical importance should be attached to smoothing of the conductor surface in cables is indicated by comparing samples *C*1 to *C*3 ("compack" stranded) to samples *D*1 to

*D*3 (strand shielded with semi-conducting tapes). The smoothness of the conductor surface in these samples increased the breakdown voltage by an average of 24 percent. In assessing the significance of this increase, the reduced effective insulation thickness in cable *D*, owing to the substitution of semi-conducting tapes for insulating tapes, near the electrodes, should be taken into account. With an equal thickness of effective insulation, this value would be nearer 30 percent.

The application of 200 psi pressure, gas or oil had a rather curious effect on the maximum stress at breakdown (samples *E*1 to *E*4). It was expected that pressure would increase the impulse strength. On the contrary the results indicated a ten percent decrease due to pressure. If the lower value had been found in only one specimen and the higher value in several specimens, the results might be ascribed to local conditions. However, the single specimen (sample *E*4) tested without pressure was found to have the highest value. Further investigation is recommended before final conclusions are drawn as to the effect of pressure on impulse strength.

Conclusions

The results of the impulse tests conducted by The Detroit Edison Company on various types of impregnated paper-insulated cables seem to indicate that with the type of impulse wave and method of application used in these tests, in a cable having the best obtainable insulation, breakdown occurs at a voltage for which the maximum stress is around 3,300 volts per mil. For a given insulation thickness, therefore, an increase in the minimum radius of the conductor and the use of smoother electrode surface should result in an increase in breakdown voltage. If the quality of the insulation is inferior, owing either to non-uniformity of taping or incomplete impregnation, or both, the maximum stress value can be expected to become less than 3,300 volts per mil. Therefore, the maximum stress obtained from impulse tests, compared with 3,300 volts per mil is a good measure of the uniformity of taping and the degree of impregnation of the insulation. The correlation obtained in these tests between the impulse strength value and the findings of visual examination, such as those shown in Mildner diagrams (also styrene wafers), shows that these visual tests in their turn can justifiably be used as a measure of the impulse strength of the cable insulation.

In view of the above mentioned results, solid, oilfilled, oilostatic, and compression cables should all have the same maximum stress at breakdown. For a given insulation thickness and conductor surface, the oilfilled cable, therefore, having the advantage of an intrinsically large diameter of the conductor will withstand the highest voltage before breakdown occurs.

The tests also indicated that this type of cable will retain this advantage even after aging. The solid, oilostatic, and compression cables, when new, belong to the same group as regards impulse strength. From the decrease of the degree of impregnation in service, it is logical to assume that service aged solid cables have a lower impulse strength than new ones and this assumption is borne out by test. By inference, it may be concluded that the care used in taping solid type cables is more important than the degree of impregnation since age decreases the beneficial effect of the latter, whereas the former will remain practically the same. Oilostatic and compression cables, on the other hand, can be expected to retain their original breakdown values even after aging, although there is as yet no direct experimental verification of this assumption. Low gas-pressure cables, although originally lower than solid-type cables as to impulse strength, are expected to retain this value after service aging and it is possible that they would then show even higher impulse strength than solid-type cables.

1. In case of a cylindrical concentric cable with smooth surfaces of conductor and sheath, the field stress (*S*) at a point of the dielectric is given by the equation

$$S=\frac{E}{r_1 \log \frac{R}{r}}\ \frac{\text{volts}}{\text{cm}} \qquad (1)$$

where

E = voltage applied between conductor and sheath

The A-C Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical Insulation

FRANK C. DOBLE
ASSOCIATE AIEE

General

THE use of dielectric loss and power factor for testing the insulation of electrical equipment in service position in the field with one side grounded began with the advent of the apparatus and method described in this paper.

Through its use, tables of standard values have been set up indicating when insulation is "good" for continued operation with an adequate factor of safety or when it is "bad" to a degree that warrants investigation and possible replacement in order to insure continuity of service until the next scheduled test.

Types of insulation that were being discarded as inherently bad, judged by their high failure record, now are being re-established as good insulation after the tests have shown the defects to be largely of a secondary nature and removable or curable.

History

A series of high-voltage bushing failures occurring about 1925 emphasized the need for developing a practical field test for this type of insulation that would indicate the presence of certain types of fault or deterioration which inherently were not detectable by a non-destructive direct-current test.

A considerable amount of research and development work was done and several methods were tried and discarded before the ultimate discovery of the a-c dielectric-loss and power-factor method.

The voltage-distribution method for testing high-voltage live-line insulators which had been in successful use for several years was first tried but this method failed to reveal many types of defective insulation that were responsible for costly service interruptions.

Apparatus was then developed for measuring the charging current of a bushing at operating line voltage by isolating on an insulating support a current instrument arranged for connection in series between the terminal of the bushing and the live line normally leading to it. This test did not reveal certain types of defects in insulation and service interruptions continued to occur.

Finally the method described in this paper was devised in which voltamperes, watts, and the power factor of the insulation were measured in the field with portable instruments. The operation and application of the apparatus during the past ten years have been described in the papers listed in the bibliography. This paper is concerned with the technical electrical features and principles involved. There are different forms in which the apparatus may be constructed. For the purpose of discussion, the details of one form of the apparatus will be used to illustrate the general principles.

Test Apparatus Elements

The elements of apparatus required in an a-c dielectric loss method for field investigation of electrical insulation are shown in figure 1.

A 110-volt supply feeds a step-up transformer, *T*.

From the high-voltage terminal of the high-voltage winding, a cable connection leads to one side of the specimen, C_xR_x, which is grounded.

The measuring means, *M*, is connected between one side of the high-voltage winding of the transformer, *T*, and the grounded specimen under test.

Technical Problems

There are special technical problems involved in apparatus designed to measure losses in insulation as installed in the field with one side permanently grounded and subject to electrostatic induction from adjacent or surrounding circuits and apparatus. Because the ground connection can-

Paper 41-132, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted November 22, 1940; made available for preprinting May 21, 1941.

FRANK C. DOBLE is president of the Doble Engineering Company, Medford Hillside, Mass.

1. For all numbered references, see list at end of paper.

---

r_1 = radial distance of the point from the center of the cable
r = inner radius of insulation
R = outer radius of insulation

Maximum stress for a given cable will be at the surface of the conductor when $r_1 = r$ and the equation will be

$$S = \frac{E}{r \log \dfrac{R}{r}} \tag{2}$$

2. For sector shaped conductors with paralleling ground (shielded cable), and smooth surface of conductor and shielding, the portion of the sector containing the points with the greatest stress, is what is known as the "shoulder" of the sector, having the minimum radius of curvature. In cables with sector-shaped conductors maximum stress was estimated by substituting these minimum radii in equation 2.

3. For elliptical (oval shaped) conductors same consideration as in 2, was applied.

4. To calculate the effect of stranding in cables other than those with compacted stranding, the following formula developed by Serguis Vesselowsky of The Detroit Edison Company was used:

$$S = \frac{0.572nE}{r\left(0.119 + n \log_{10} \dfrac{R}{r}\right)} \tag{3}$$

where

n = number of strands in outer layer
E = voltage applied between conductor and sheath
r = inner radius of insulation
R = outer radius of insulation

Above formula appears to be sufficiently accurate for high values for n (greater than 6).

5. In case of compacted stranding, the maximum value should be somewhat higher than that found in similar cable with smooth conductor surface. However this type of conductor does not lend itself to ready calculations because of differences of smoothness of conductor surface.

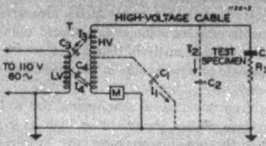

Figure 2. Simplified circuit diagram showing charging currents originating in the test apparatus itself

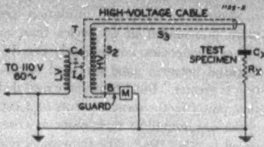

Figure 3. Test circuit diagram with shields to divert I_1, I_2, I_3

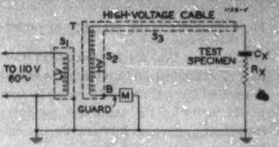

Figure 4. Test circuit diagram with shields to divert I_1, I_2, I_3, I_4

not be removed or even temporarily disconnected, the measuring means cannot be connected between the specimen and ground, and so cannot be connected directly in series with the insulation it is desired to measure. Consequently, the permanent ground limitation may cause the measuring apparatus to be subjected to electrical influences other than the losses in the insulation. For example, there may be:

Charging currents originating in the measuring apparatus itself.

Changes in phase angle and current caused by variations in capacitance.

Effects from extraneous electric fields.

Charging Currents Originating in the Apparatus Itself

In figure 2 the charging currents originating in the apparatus itself are indicated on a simplified diagram of the test equipment without any shielding. The distributed capacitance between the high-voltage winding of the transformer and ground is represented by a single capacitance, C_1, and the resulting charging currents are represented by I_1. The distributed capacitance which extends the entire length of the high-voltage cable is shown conventionally as a single capacitance, C_2, and the charging current as I_2. The distributed capacitance and current from the high-voltage end of the 10,000-volt coil of the transformer are shown as C_3 and I_3. Likewise the distributed capacitance and current between the 110-volt coil and the low-voltage end of the 10,000-volt winding are shown as C_4 and I_4. All of these charging currents, I_1, I_2, I_3, and I_4, flow through the measuring means, *M*, in addition to the current through the specimen which alone it is desired to measure. It is realized that these currents involve both capacitance and loss components but for brevity they are referred to as charging currents.

In figure 3 there have been added to the circuit of figure 2 guard shields S_2 and S_3 around the high-voltage winding of the transformer and the high-voltage lead. Charging currents I_1, I_2, and I_3 are diverted from the measuring means, *M*, by these shields, but I_4 continues to flow through *M*.

In figure 4 there has been added to the circuit of figure 3 a grounded shield S_1 around the low-voltage winding of the test transformer. This shield, S_1, diverts charging current, I_4, from the measuring means, *M*. This is important because the phase displacement of I_4 may be such that it will cause large errors in the watts measurement.

Changes in Phase Angle and Current Caused by Variations in Capacitance and Effects From Extraneous Electric Fields

From a study of figures 3 and 4, it is obvious that the capacitance between ground and the shields S_2 and S_3 is in parallel with the measuring means, *M*. This capacitance shunt diverts some of the test specimen current away from *M*. Correction for this shunting effect can be made by means of a compensating circuit or network. If this shunting capacitance is kept substantially constant, need for adjusting the network is practically eliminated. One method for maintaining constant capacitance is shown in figure 5 where, in addition to the shields S_1, S_2, and S_3 there are grounded shields S_4 and S_5 which surround the guard shields S_3 and S_2 on the high-voltage cable and the apparatus. Means for compensating the shunting effect are provided by the adjustable network *R* and *C*.

An additional function of the grounded shields S_4 and S_5 is to prevent currents induced from extraneous sources from flowing through the measuring means. By reference to figures 3 and 4, it will be seen that currents induced in the shields S_2 and S_3 from extraneous sources, such as adjacent high-voltage circuits, would flow to ground through the measuring means, *M*, thus vitiating the measurement. The shields S_4 and S_5 conduct such currents directly to ground.

This grounded shielding also contributes greatly to the safety of the operator by providing a direct path to ground for stray currents due to accidental breakdown of the insulation of the test circuit or contact with external high-voltage sources. In actual practice, lives of operators have been saved by this ground shielding when defective operating mechanism caused bushings under test to be accidentally alive at line voltages.

Even with the test apparatus and the test cable protected from external fields, the bushing or other test specimen may be so positioned as to have a considerable voltage induced at its high-voltage terminal due to extraneous sources. Voltage so induced in the specimen may in turn produce currents to ground which will flow through the measuring instruments, and it is essential to have means in the set itself for making corrections for these effects. A reversing switch, *SW* (figure 5), performs this function.

In practice, if the test voltage is less than 90 degrees out of phase with the current induced in the test specimen due to external fields, the resultant current and watts, as determined by the instruments, will be too great. If, however, the phase of the induced current is more than 90 degrees out of phase with the test potential, the watts and current indicated on the instruments will be too small. The actual value of watts loss in the insulation under test may be determined by taking two readings, first with the reversing switch in one position and then in the other. The algebraic average of these two readings is the actual watts loss in the specimen, and the algebraic average of the current is substantially the current flowing through the test specimen due to the test voltage. Thus, power factor can be calculated from watts-loss and current values determined under severe conditions of interference.

For example, let W_1 and W_2 be the observed values on the wattmeter, and I_1 and I_2 be the current readings, with the reversing switch first in one position and then in the other. The algebraic average of the watts loss will be $\frac{W_1+W_2}{2}$, and the algebraic average of the current will be $\frac{I_1+I_2}{2}$.* The resulting power factor will be $\frac{W_1+W_2}{E(I_1+I_2)}$. The accuracy of power-factor values thus derived from field readings of watts loss and voltamperes is well illustrated by a comparison with the true power factor of the same test specimen free from induction interference, as follows:

---

* In practical application it is found that the current from induced voltages is small in comparison with the current through the specimen due to the test voltage, and hence its effect on the phase of the test current may be disregarded.

Observed values in the field:

$E = 10{,}000$ volts
$W_1 = 1.9$ watts
$W_2 = -1.6$ watts
$I_1 = 895$ microamperes
$I_2 = 685$ microamperes

The formula $\frac{W_1+W_2}{E(I_1+I_2)} =$

$$\frac{1.9+(-1.6)}{10{,}000(895+685)10^{-6}} = 1.9\% \text{ power factor}$$

True power factor, no induction $= 2.0\%$.

In passing it is interesting to note that it is not possible to compute the correct power factor by averaging power factors obtained under conditions of electrostatic interference by direct and reversed connections of the test voltage respectively. The algebraic expression for averaging power factor would be $\frac{\frac{W_1}{EI_1}+\frac{W_2}{EI_2}}{2}$, which equals $\frac{W_1I_2+W_2I_1}{2EI_1I_2}$. Applying this formula to the example cited above gives:

$$\frac{1.9(685)(10^{-6})+(-1.6)(895)(10^{-6})}{20{,}000(895\times10^{-6})(685\times10^{-6})} = -1.1\% \text{ power factor}$$

which negative result obviously is incorrect and in this case meaningless.

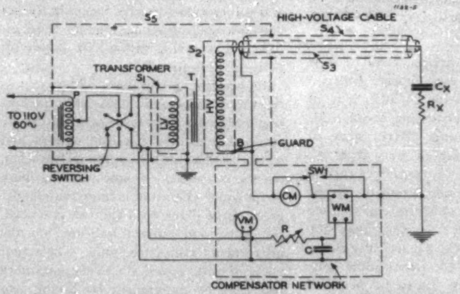

Figure 5. Simplified diagram of the watts-loss and power-factor tester

Test Frequency—60 Cycles

A test frequency of 60 cycles is most desirable because, other things being equal, a test at normal operating frequency reflects actual operating conditions. Moreover, the power factors due to defects in composite insulation are more pronounced at 60 cycles than at higher frequencies, consequently the differential between good and bad insulation is greater. Field trials have revealed that power-factor measurements at 1,000 cycles are limited in their scope as compared to 60 cycles.[8] The thousand-cycle power-factor test proved inadequate to indicate types of serious deterioration which were readily found by the 60-cycle power-factor test.

Test Voltage

A successful field testing apparatus requires a test potential adequate to detect deterioration in insulation of all voltage ratings up to and including the highest kv rating in practical use, which at the present time is 287 kv.

In practice, the operating company is interested principally when insulation has deteriorated to a point where it has become a failure hazard or represents a radio interference problem.

From a design standpoint the manufacturer is interested also to learn of inherent defects or incipient faults which may ultimately cause deterioration even though the resulting destruction of insulation value may not represent an electrical failure hazard until after many years of service operation.

Considering specifically the manufacturers' interest in new design, a test potential equal to or higher than operating voltage might furnish valuable data if it were possible in the field to separate the true loss from abnormal losses due to corona and extraneous interference conditions. However, except for studies of new design the advantages to be derived by the use of over-voltage in routine field testing are heavily outweighed by its obvious disadvantages. Extensive investigation of bushing insulation in the field showed that power-factor measurements at over-voltages introduced complications of analysis that are of no immediate practical value to the power company.

From a technical standpoint, the test voltage chosen should be as high as efficiently possible to meet the requirements of surface contact difficulties, ample unit stress on the insulation under test, and the minimizing of extraneous influences. On the other hand, the difficulties of segregating corona losses from insulation losses and the problems of portability, power supply, and regulation (all of which increase with voltage) compel a compromise in the interest of economy and efficiency. Tests at 10 kv appear to avoid a maximum of the difficulties. Data from ten years' experience with field tests on insulation rated from 10 kv to 287 kv indicate that a 10-kv test potential is adequate to solve the operating maintenance problem and also to make contributions useful to the manufacturer in his design problems.

COLLAR TESTS

Need for localized high-voltage stress under special conditions, such as occur in voids in compound-filled bushings, is met by applying a metal band or "collar" to critical parts of the insulation so that the application of 10 kv produces higher unit stress at these local parts than would be produced by a test at full line voltage on the insulation as a whole. For example, tests at 10 kv impressed on metal collars placed under the first or second petticoat of a bushing will produce stresses that will indicate the presence of moisture, voids, and other abnormal and deleterious conditions in their incipient stages. In testing compound-filled bushings, the power-factor measurement is almost universally supplemented by the collar test. The trend of both measurements is carefully tabulated from consecutive tests and both are taken into consideration in the final analysis of the bushing condition.

Test Apparatus Details

In the particular circuit illustrated by figure 5, it will be noted that the measuring means consist of a voltmeter, wattmeter, and current instrument. In the following description (to differentiate this set from other types of measuring equipment which could be used), this equipment will be referred to as the "watts loss and power factor apparatus."

Figure 6 is a wiring diagram of a complete watts loss and power factor insulation test set, shown pictorially in figure 7.

The multi-shielded cable has four concentric conductors separated by graded insulations of 500 volts, 10,000 volts, and 500 volts, respectively.

Safety

Important safety features shown in the circuit diagram include a protective relay, series switches, and a safety grounded shielding system surrounding the entire test apparatus including the high-voltage test cable except a hook at the end for contact with the test specimen. Danger from contact with the test voltage is practically eliminated since the hook is the only exposed live part. The arrangement of the shielding is particularly effective in protecting the test operator against trouble arising outside the test apparatus itself, such as the remote but extremely dangerous possibility of accidental direct contact of the hook with the live line, or possible abnormal conditions due to serious voltages induced in the test circuit by short-circuit or ground occurring in neighboring equipment.

Range of Test Apparatus

The testing range of the apparatus described in this paper is from 0 to 2,000 milliamperes, or 2 amperes, at 10 kv.

To meet more special testing conditions, the apparatus has been adapted to convenient ranges of 10, 30, 150, and 2,000 milliamperes. The larger ratings are used for testing power transformers and cables. The design and physical dimensions of the apparatus are substan-

Figure 8. Testing a 220-kv bushing of the draw-lead type independent of the winding in a 220 / 110 / 13-kv transformer with the 30 tester and hot-guard attachment

tially the same up to and including 150 milliamperes, beyond which range additional equipment is required.

Auxiliary Test Equipment

For special tests a shielded current transformer, called "hot guard" transformer, is used in combination with regular testers. For example: in addition to making an overall test on a power transformer, it is advantageous to be able to test the transformer bushings individually without disconnecting the windings at the lower end of the bushing under oil. For this purpose, when the transformer winding terminates in a draw lead through the bushing, a "hot guard" attachment is used to supplement the regular test equipment. Figures 8 and 9 show a set with the "hot guard" attachment arranged for making tests on a transformer bushing in a 23,000-kva transformer. In this apparatus, a shielded current transformer, *CT*, is inserted in series with the high-voltage lead so that transformer bushings of the draw-lead type readily can be measured independently of the transformer winding. The test voltage is applied between the metal tube electrode *A* and ground and only current flowing from this electrode *A*, through the insulation of the bushing, to ground actuates the measuring instruments by flowing through the transformer primary, *W*.

By means of the guard circuit S_6S_7 which is connected to the lead of the transformer at *L*, the charging current flowing into the winding of the transformer through the capacitance *CW* to ground is by-passed from the measuring instruments. The wiring diagram of the "hot guard" test set as adapted to testing transformer bushings is shown in figure 9. It will be noted that the guard circuit, S_6S_7, which by-passes the current transformer winding is at nearly the same potential as that applied to the specimen. Thus, for test purposes, the insulation between the draw lead and the bushing tube need be only sufficient to withstand low voltage. In the test cable already described in connection with figure 6, the concentric (hot guard) shield nearest the center conductor is provided for this special test, and during a "hot-guard" test another shield, called the cold-guard shield, is connected to ground.

For testing generators and cables requiring charging currents up to 2 amperes at 10,000 volts, a shielded resonating choke is connected directly across the high-voltage winding of the test transformer and adjusted until the inductance of the choke and the capacitance of the test specimen are anti-resonant at 60 cycles. Under this condition the test transformer is required to supply only the losses in the choke-specimen resonant system, and 2 amperes at 10,000 volts may be obtained with a supply to the 110-volt side of the transformer of only 20 amperes which easily can be obtained from an ordinary lighting circuit. Without the choke the corresponding current on the 110-volt side of the transformer would be about 200 amperes which is very difficult to obtain in practice, and its complete regulation by portable equipment practically is an impossibility.

Application of Tester

The technique of applying the tester to the varied forms of insulation as found on the modern power system has been thoroughly covered in the literature of the AIEE,[1,2,3,4] and other publications,[5,7,9,10,11] listed in the bibliography.

Designed primarily for a bushing problem, the successful results in this investigation led to an extension of the application of the tester until it is now used for checking the condition of all types of insulation in service position, and also for acceptance tests on new and reconditioned insulating structures.[1,2,3,4]

Test Data and Their Interpretation

The criteria used for rating the serviceability of insulation from field dielectric-loss and power-factor tests are derived from the correlation of thousands of field tests, and many investigations. They are based on certain well known facts about insulation.

The correct interpretation of field dielectric-loss tests requires a knowledge of the detailed construction of the apparatus being tested and the characteristics of the particular types of insulation used. For example, each type of bushing has certain characteristics peculiar to its construction; defective internal insulation of an oil circuit breaker shows up in different ways depending upon the breaker construction.

The dry type porcelain bushing is subject to corona formation which must be considered in analyzing the test data. The condenser type bushing may show a normal power factor but have several condenser layers shorted out; this is revealed by an increase in charging current (capacitance) during the routine dielectric-loss test. A decrease in charging current for some types of compound-filled bushings indicates a break in the ground shield connection. The oil-filled type bushing may have a high power factor as a result of deteriorated oil; if the oil is replaced promptly, there may be no injurious after-effects. Collar tests will reveal defects in compound-embedded bushings that otherwise would be masked.

The condition of the internal insulation of an oil circuit breaker is revealed by a comparison of the sum of the watts loss for the two bushings in a tank during the open-breaker test, with the combined loss of these same two bushings during the closed-breaker test. A study of these data will indicate defective lift rods or flash barriers, defective cross braces, wet or dirty de-ion grids, and many other forms of operating hazards.

No piece of insulation should be condemned until it has been completely isolated, cleaned, and compensated for temperature. Experience has shown that approximately two-thirds of the cases of high over-all dielectric loss initially found are due to bad operating condition such as carbon deposit, etc., that can be removed by ordinary servicing.

Standards for evaluation of test results appear in the literature,[2,3,4,7,9,11] as well as voluminous data concerning the results of their application to the insulation tests of typical operating companies.[1,2,3,4,5,7,9,10,11]

Typical test results[2] have indicated that defective equipment testing high enough to be removed from service is distributed among various types of apparatus in the following order:

	Percentage in "Remove" Class
Oil circuit breaker bushings..	2.1
Oil circuit breaker tank faults	1.6
Transformer bushings.........	3.2 to 3.9
Spare bushings.....................	8.8
Instrument transformer windings....	7.7
Power transformer windings.........	3.1

By the use of the technique and apparatus described, defective insulation can be detected in time for removal from service before it fails.[1,2,3,4,5,7,9,11] Such anticipation of failures not only prevents service interruptions but also makes possible the rehabilitation of defective insulation which otherwise might have been destroyed.

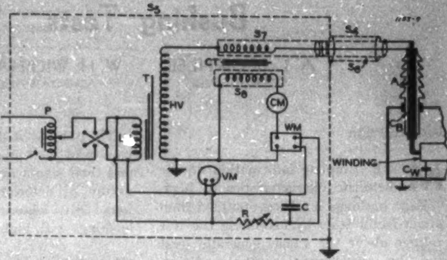

Figure 9. Schematic diagram of the essential portions of the tester circuit when the shielded current transformer "hot guard" is employed for testing transformer bushings of the draw-lead type

Of a large number of bushings tested and indicated defective to a point needing attention, about one-half of the faults were found to be external to the main insulation of the bushing and a considerable percentage of the faults that are in the main insulation can be cured or improved by servicing.[7]

"Insulation faults develop in all types of equipment such as bushings, transformers, wood insulation, and oil regardless of equipment design as it exists today. These faults may develop critically within test period intervals of 18 months to two years, as shown by the experience cited above, and appear, in a few cases, to develop to a lesser degree in a shorter period of time. Periodic testing, therefore, is necessary if a high standard of insulation is to be maintained."[2]

Conclusions

The use of the apparatus and method described in this paper makes it possible successfully to measure the a-c dielectric loss and power factor of all types of high-voltage insulation in service position. Such measurements provide an adequate non-destructive method for economical maintenance of insulation and for detecting deterioration in time to prevent failure.[4] The use of the equipment for tests at regular intervals and proper interpretation of the results will reduce to a minimum service interruptions due to faulty insulation.[2] Experience has proved that the period between tests of equipment in important locations should not exceed one year.[4]

Introduction

MORE complete information on the dielectric characteristics of high-voltage bushings has been obtained from power-factor tests by extending the test voltage above the values generally used and by supplementing the ordinary power-factor tests with laboratory examinations of deteriorated bushings.

Most power-factor tests on high-voltage bushings have been made at a relatively low voltage, about 10 kv, regardless of the operating voltage of the bushing. These tests have been valuable in determining the general condition of the insulation. But by extending the test voltage to higher values, even above the operating voltage, it has been possible to detect defects in new bushings which would shorten their useful life and to detect certain types of deterioration in older bushings, both of such a nature that they are not shown by a low-voltage test.

Laboratory examinations of deteriorated bushings have been valuable in determining the nature, extent, and cause of bushing deterioration. Such information is needed to properly evaluate power-factor test results.

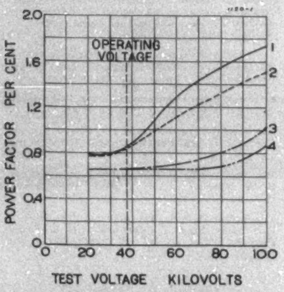

Figure 1. Power factor versus voltage curves, 66-kv condenser-type bushings

The purpose of this paper is to give the results of tests made at higher voltages and their significance and to describe the nature of deterioration in bushings as found by laboratory examinations of bushings with high power factor.

High-Voltage Power-Factor Tests

Power-factor tests on bushings at voltages equal to or above the operating voltage have shown defects in new bushings which would not have been found by a low-voltage test.

Ionization in two new 66-kv condenser-type bushings at a voltage below their operating voltage is shown by the sharply rising power-factor vs. voltage curves No. 1 and 2 in figure 1. Curves No. 3 and 4, taken on similar bushings, are given for comparison and show satisfactory power-factor-voltage characteristics. Curves 1 and 2 show an abnormal increase in power factor with voltage. Corona was present within these bushings at their normal operating voltage, 38 kv, as indicated by the breaks in the curves below that point. The ionization probably occurred in voids in the insulation which may be formed by wrinkles made in wrapping the paper which forms the condenser layers. The photograph of figure 2 shows a condenser-type bushing which was dissected and showed such wrinkles.

Corona has a deleterious effect on the insulation. Discoloration of the insulation around voids has been found in bushings which have been dissected. The action of corona will, in time, produce weak spots in the insulation and might lead to ultimate failure. New bushings in which corona is present at the operating voltage, as shown by high-voltage power-factor tests, are not acceptable.

Power-factor tests at these higher voltages have also shown up deterioration in older bushings which would not have been found by a low-voltage test.

The partial failure of a 44-kv condenser-type bushing is shown by the power-factor and capacitance vs. voltage curves of figure 3. The increasing power factor with increasing voltage, together with the abrupt change in capacitance above 60 kv. indicate that the insulation of one of the condenser layers was deteriorated so that it became partially conducting at the higher voltages. This was confirmed by measurements on the individual layers as given in table I. The outer layer had a very high power factor, 29.6%, compared with an average of 1.65% on the inner seven layers. The high power factor of the outer layer was found to be confined to the area under the ground flange as shown by the curve of figure 4 which gives the power-factor variation longitudinally over the outer layer. The insulation of this outer layer had become contaminated with glycerine from the litharge and glycerine cement used in cementing the ground flange to the condenser.

Partial failure of an oil-filled bushing is shown by the power-factor and capacitance vs. voltage curves of figure 5. While the fault had progressed so far that the power factor was high even at the initial voltage of 10 kv the increasing capacitance with increasing voltage and the changing power factor indicate the nature of the fault—a carbonized path within the bushing. The lower ends of the four inner insulating barriers between the conductor and the equalizing shield were badly burned and heavily carbonized. This conducting path gave rise to the high power factor and to the changing characteristics with increasing voltage.

Laboratory Examinations

Laboratory examinations have been useful in determining the penetration of moisture in bushing insulation and the effectiveness of drying methods. Figure 6 shows a sketch of a 66-kv condenser-type bushing which had a high power factor due to moisture absorption and table II gives the results of the examinations made to determine the distribution of moisture in the insulation and the effectiveness of drying. The power factor of this bushing was not reduced by drying at atmospheric pressure; on the contrary,

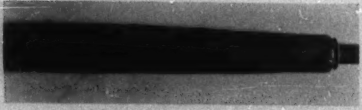

Figure 2. Condenser-type bushing with outer layers of insulation removed

---

Paper 41-120, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 14, 1941; made available for preprinting May 15, 1941.

A. L. Brownlee is meter engineer and W. H. Wickham assistant engineer, electrical measurements, with Commonwealth Edison Company, Chicago, Ill.

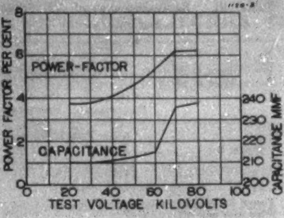

Figure 3. Power factor and capacitance versus voltage curves, 44-kv condenser-type bushing

it increased slightly. Moisture had entered the top of the bushing. This was confirmed by separating the ground wire into two sections, *A* and *B* of figure 6, and measuring the power factor to the upper and lower parts. The power factor was higher under the upper part, *A*. Further drying reduced the power factor somewhat because the separation of the outer layer between *A* and *B* afforded the moisture a means of escape. By measurements on the condenser layers it was established that moisture had penetrated to the second outer layer and that the inner eight layers had not been affected. Also, after prolonged drying at atmospheric pressure the second outer layer still contained a considerable amount of moisture.

Drying under vacuum has been much more effective in reducing high power factors caused by moisture. The curves of figure 7 show the results of drying four condenser-type bushings in vacuum The power factors of all four were reduced to satisfactory limits in reasonable time.

While moisture has generally been considered the chief cause of high power factor in bushings, laboratory examinations have also shown contamination from substances other than moisture.

In the 25-kv solid-type bushing sketched in figure 8*A*, the impregnated paper had been contaminated by acid compounds formed by deterioration of the varnished cloth. The variation of power factor longitudinally is shown in figure 8*B*, curve 1. The power factor was highest in the area under the ground shield. Curve 2 was taken after removing 0.2" of the outer paper and curve 3 after removing 0.1" more. A comparison of these curves shows that the power factor was highest in the outer part of the impregnated paper which was nearest the varnished cloth.

In a 37-kv solid-type bushing shown in the photograph of figure 9, the impregnated paper had been contaminated with a mixture of oil and filling compound. The power factor of this bushing was 9%.

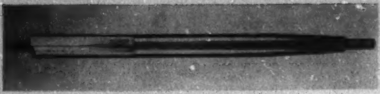

Figure 9. Solid-type bushing with section of insulation removed to show contamination

The path of oil up through the bushing can be seen at the lower end (left). The dark portion in the center shows the penetration of dissolved filling compound from the top

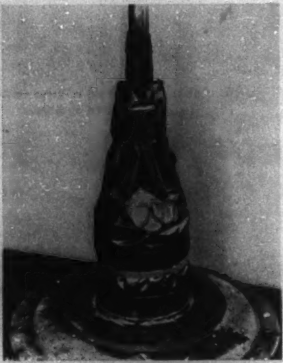

Figure 10. Oil-filled bushing, porcelain-barrier type

View of internal parts showing deposits of disintegrated varnish compounds at the top and of litharge in the folds of the varnished cloth near the center

Power-factor tests on sections of the bushing showed that the power factor was 37.2% at the upper end above the ground shield and 1.78% at the lower end. Examination of a longitudinal section of the insulation showed that oil had migrated from the lower end, through separations in the impregnated paper, to the compound in the top. Compound dissolved in the oil had penetrated the insulation from the upper end. The paths of the oil and compound can be seen in the photograph.

Contamination of the oil has been found in oil-filled bushings of the porcelain-barrier construction. In one instance a 66-kv bushing of this type had a power factor of 26.1%. The power factor of a sample of oil was 84.9% and the dielectric strength of the oil was 14 kv. A photograph of the interior of this bushing is shown in figure 10. Examination showed deposits of disintegrated varnish compounds from the varnished cloth with which the conductor and the ends of the barriers were wrapped. Also, there were heavy deposits of litharge from the litharge and glycerine cement which was used to cement the barriers together.

Deterioration of oil and of impregnated paper under oil has been found by examination of oil-filled bushings of impregnated-paper barrier construction. Table III shows the results of examination and test of the component parts of two 66-kv bushings of this type. On No. 1 the power factors of the core and the barriers were satisfactory. Evidently deterioration of the oil gave rise to the power factor of 2.47% since the power factor was reduced to 0.49% using the same impregnated-paper parts with new oil. On No. 2 the impregnated paper of the core had a high power factor which was not reduced by drying. The insulation had become contaminated by the products of deterioration in the oil. The core was replaced.

Table III. Reconditioning of Oil-Filled Bushings

	Volume, Percentage	Surface, Percentage

Summary

The value of power-factor tests on bushings at higher voltages has been demonstrated. Tests at low voltages, while valuable, are inadequate. The power-factor and capacitance vs. voltage characteristics at voltages up to or above the operating voltage are important in judging the condition of the insulation.

The nature of bushing deterioration and the significance of high power factor have been shown by laboratory examinations. The findings help to establish a basis for power-factor limits, and for improvements in design and maintenance.

Excitation Circuits for Ignitron Rectifiers

H. C. MYERS
NONMEMBER AIEE

J. H. COX
ASSOCIATE AIEE

Introduction

THE development of the ignitron type of mercury arc rectifier, with its outstanding advantage in efficiency, introduced the need of a new type of excitation circuit. For the theory of how the arc is initiated, the reader is referred to the previous papers on ignitrons.[1,2]

Associated with each anode of an ignitron rectifier is an ignitor for initiating the arc. Each ignitor requires a positive impulse of current once each cycle to start the arc at the beginning of the conducting period of the main anode. In order to accomplish control of the output voltage of the rectifier, it must be possible to adjust the phase position of these impulses with respect to the supply voltage, either manually or by automatic provisions. Although the instantaneous current and power of the impulses are quite high, the impulse duration may be such that the average power is low and does not seriously affect the efficiency of rectifiers with the ratings usually encountered.

If an excitation system such as "main anode" is used with which only enough energy is applied to the ignitor each cycle to ignite the arc, the average power is very small. However, with separate excitation systems, every impulse must have the same energy and this must be adequate to ignite the arc under the most adverse conditions encountered.

The wave shape of the impulse is not critical, but the peak value of power required for reliable excitation varies considerably with the time rate of rise of current. With a high rate of rise, the voltage at which a cathode spot is formed is higher than if the voltage is applied more slowly. For a given rate of rise, this voltage varies somewhat from cycle to cycle, depending upon the exact condition of the contact of the mercury and the ignitor. This, of course, influences the time of pick-up of the main anode, so the impulses must be steep enough so that any such variations are negligible.

With the assumption that the impulses have the shape of the positive half of a sine wave, figure 1 has been plotted to show the average power of 60 impulses per second applied to a load with impulses of various peak powers and durations. The duration of the impulses is indicated by the base of the wave in terms of degrees of a 60 cycle wave. The values given by the curves must be increased by the losses in the circuit elements to obtain the total power requirements for excitation. The various systems have varying efficiencies. Circuits with which the authors have had experience have varied in their total power requirements from 75 to 300 watts per ignitor.

There are four types of ignitron excitation circuits that have been used quite extensively in commercial applications which might be termed as follows:

(1). main anode
(2). capacitor-thyratron
(3). rotating impulse generator
(4). saturating reactor

All of the above have been applied with variations, as the art progressed, and depending upon the application. The following is a list of some of the circuits that have been worked on experimentally, but as yet have not proven sufficiently attractive to be applied commercially:

(1). peaked-wave transformers
(2). sine wave transformers phased back with thyratrons
(3). multi-anode control rectifier
(4). rotating commutator or other contact mechanism

A disadvantage of all circuits using thyratrons is that these tubes, having thermionic filaments, have limited life and constitute a replaceable item. An advantage, of course, is that voltage control is extremely flexible, simple, and efficient, since voltage control can be obtained by control of the thyratron grids. This control can consist of a bias voltage on the neutral of a sine wave grid transformer or a phase shifter in the primary of either a sine wave or a peaked wave grid transformer. A suitable phase shifter consists essentially of a wound rotor induction motor with the rotor locked in the desired phase position.

The conventional thermionic cathode of a thyratron is an average rated element; it is not suited to high over currents and thus not best suited to ignitron excitation. Ignitors require relatively high currents for short times. If only average currents were involved, ignitron excitation could be accomplished with very small and inexpensive thyratrons.

For purposes of reliable anode pick up, as well as certain control functions, it is desirable to provide a small excitation current to the main anode shield. Since this is only a nominal amount of power, it can be taken from any of the readily available sources. The figures used to

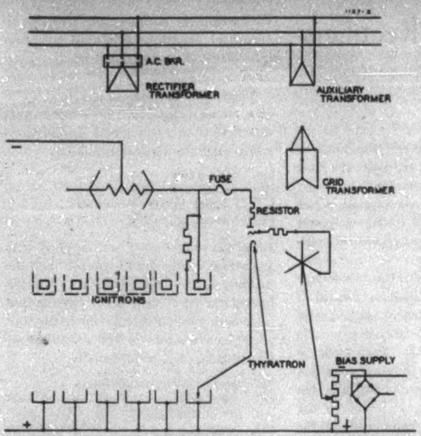

Figure 2. Diagram of a double three-phase ignitron rectifier with main anode excitation and bias control

illustrate the various excitation systems show the shield excitation accomplished in a variety of ways.

Main Anode Excitation

Figure 2 shows a schematic diagram of a simple anode fired ignitron rectifier using a grid bias method of control. A conventional double three-phase rectifier circuit is indicated for the power connections. The excitation circuit is completed for only one phase since the others are duplicates.

In this system, when an anode becomes positive with respect to its cathode, if the thyratron grid is positive, current is passed through the shunting thyratron and ignitor circuit. When this current reaches the value at which the cathode spot is formed by the ignitor, the main anode picks up and the thyratron path is short-circuited by the arc. The rate of application of voltage on the ignitor is a function of the voltage of the rectifier and the amount of grid delay used. The ignitor voltage collapses sharply when the main anode picks up. In this circuit only sufficient energy to ignite the arc is used each cycle and the average excitation power is very small. The major portion of the loss is the power required for heating the thyratron filament. Also, there is ample power available, since it comes from the rectifier transformer.

Although this system is highly efficient and most positive in action, it has certain limitations. Since the ignition voltage must come from the main transformer, arc pick-up does not take place until the anode voltage has reached ignitor voltage. This voltage is such that a 300 volt ignitron rectifier with anode firing operates at a minimum grid delay of approximately 8 degrees. Furthermore, because of the cycle to cycle variation in ignition voltage, this delay angle is not strictly uniform. This tends to cause some unbalance between main anodes, between phase groups, and between more than one rectifier on the same bus, all at low loads. At loads of one-quarter full load and higher, this effect vanishes.

In this circuit the ignition current must also pass through the load. Therefore, at loads below ignition value the entire load current passes through the thyratrons. Actually this is not very important since currents below ignition currents are well within the limits of the thyratrons used, even though maintained for the full load-conducting period.

With main anode excitation, the duty on the thyratron is probably more severe than in separate excitation circuits using thyratrons, since in the former, if an ignitor does not pick up, the current in the thyratron is limited only by the load demands, the resistance in the thyratron ignitor circuit, and the collapse of the interphase transformer voltage.

Capacitor-Thyratron Excitation

Figure 3*a* shows an excitation circuit in which a capacitor is charged through a resistor from a sine wave transformer. At a point near maximum positive charge the capacitor is discharged through the ignitor by triggering the thyratron. The principal voltage and current waves are shown in figure 3*b*. The front of the wave produced is very sharp and the tail is determined by the capacity and resistance of the circuit. The front can be sloped if desired by placing an air core reactor in the discharge circuit.

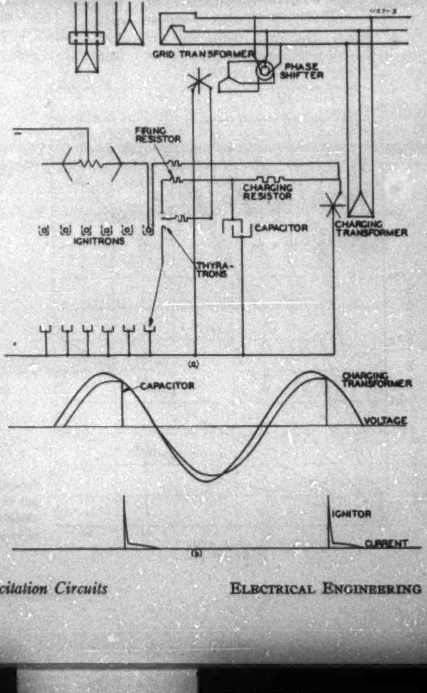

Figure 3. Ignitron rectifier circuit using capacitor - thyratron excitation with resistance charging

(*a*) Circuit diagram

(*b*) Voltage and current waves

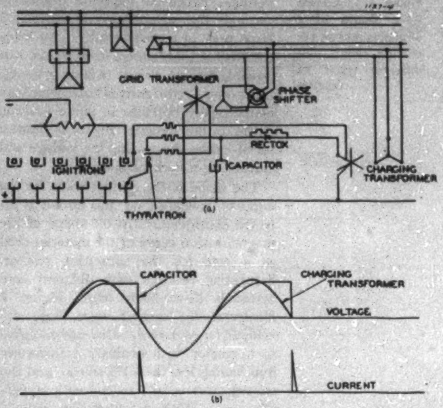

Figure 4. Ignitron rectifier circuit using capacitor - thyratron excitation with Rectox charging

(*a*) Circuit diagram
(*b*) Voltage and current waves

This circuit is simple and direct, and has the advantage of some follow-up current from the charging transformer after the pulse, which maintains an arc for 30 or more degrees and aids pick up of the main anodes at very low loads where the interphase transformer does not function. However, since the capacitor is charged through a resistor and this resistor must limit the follow current, the circuit is limited in the voltage that can be used without prohibitive loss.

The circuit permits a grid delay range of approximately 60 degrees. If a greater delay angle is desired, a transfer switch is necessary to shift connections between the charging transformer phases and the thyratrons. The power consumption can be reduced somewhat by using a reactor in place of the charging resistor. However, with a reactor the range of grid delay is considerably less and the power saved does not justify its use.

A modification of the capacitor-thyratron circuit, in which the capacitor is charged through a Rectox instead of a resistor, is shown in figure 4. This method of charging reduces the power requirements by about 50% and permits a wide range in choice of voltage with a corresponding range in impulse power. The power drawn from the line for either circuit has a power factor of nearly unity.

This circuit permits a wide range of grid delay, without switching terminals. However, if a wide range is used, it cannot be done with a grid bias, but it is necessary to use a phase shifter and a peaking transformer.

Impulse-Generator Excitation

By using concentrated fields and a suitable distribution of armature winding, a rotating synchronous generator can be built which produces impulse voltages. Such a winding arrangement, together with the waves produced and the connections to an ignitron rectifier are shown in figure 5. The impulses produced by units that have been built have a length of about 20 degrees on a 60 cycle base.

Grid delay with this type of excitation is obtained in either of two ways. In one, the generator is driven with a wound rotor induction motor, the necessary d.c. field being provided by d.c. in a pair of the windings. The phase position of the rotor is shifted by shifting the d.c. excitation from one to another of the pairs. Another method is to use a synchronous driving motor with frame shifting equipment.

The impulses provided by rotating impulse generators are highly satisfactory for ignitron excitation and the power requirements compare favorably with other types of efficient separate excitation systems. Furthermore, there are no replaceable parts except field brushes within the normal life of small synchronous M-G. sets.

The impulse generator has the disadvantage of being a rotating device somewhat bulky and noisy. For some applications a more serious objection is the synchronous motor's tendency to hunt and the reflected effect on the output voltage of the ignitron rectifier. By suitable choice of driving motor, this tendency to hunt can be kept to a value having negligible effect on the load where the rectifier capacity is small compared to the supply system. However, where

the rectifier load is so large that fluctuations in the load affect the frequency of the supply system, it is possible for the natural periods of the impulse generators and the supply system to be such that violent fluctuations build up. Since the size and maintenance features of impulse generators limit their attractiveness to large installations, the danger of hunting practically precludes their use.

Saturating-Reactor Excitation

Figure 6*a* shows a circuit, utilizing reactors and capacitors, which will produce power impulses suitable for ignitron excitation. The linear reactor in this circuit has an iron core with an air gap and is designed to have a constant reactance for various voltages up to the rated voltage and frequency of the circuit. For a 60 cycle circuit, this reactance is approximately 30% of the reactance of the firing capacitor. The saturating reactor is built with a closed iron core and a winding such that at the rated voltage of the circuit, it will draw a large peak of magnetizing current. This peak of magnetizing current occurs when the capacitor, C_F, is charged to its peak value of voltage; hence the capacitor discharges through the saturating reactor and a large peak of current results. By using the Rectox units shown in figure 6*a*, it is possible for one circuit to supply excitation power to two ignitron tanks which are diametrically opposite in phase position in the rectifier circuit. Figure 6*b* shows a set of curves illustrating the voltage and current for a cycle of operation.

The shape of the current wave for the impulse developed by this circuit is affected considerably by the shape of the magnetization curve of the material used as a core for the saturating reactor. Saturating reactors with different core materials have been tried. Figure 7 illustrates the current wave shape developed for each case. One curve applies to a reactor with ordinary transformer iron having less than 1% silicon, and the second curve is for a reactor with Hypernik core. With a saturating reactor using a Hypernik core, it is possible to develop a peak power one hundred times the average power input. Some tests were made using this circuit with a resistor load to show the peak voltage and current it could develop for various values of constant resistance, and the results are plotted in figure 8.

In this circuit, the phase position of the impulses, which control the ignitron voltage, must be controlled by shifting the input voltage to the excitation circuit. This may be accomplished by means of a phase shifter which must shift the entire excitation power. The phase shift-

X_P = parallel reactor

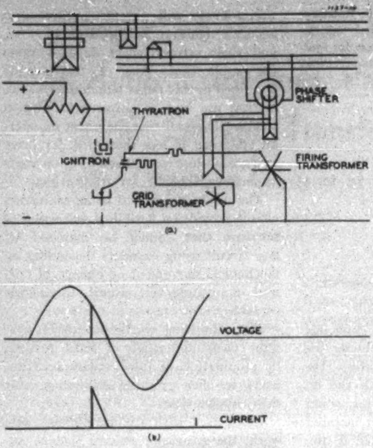

Figure 10. Ignitron rectifier circuit with sine-wave phased-back excitation

(*a*) Circuit diagram

(*b*) Voltage and current waves

ing may also be accomplished by means of a phase shifting network. Figure 9*a* shows a diagram of such a network.

The phase shifting circuit contains all the elements of the circuit shown in figure 6*a* with three additional components. The phase shifting reactor is capable of a gradual change in reactance over a 10 to 1 range by means of d.c. saturation. The parallel reactor and capacitor operate with a circulating current larger than that drawn by the excitation circuit and act as a power source for that circuit. The phase position of the voltage across the parallel combination can be adjusted by controlling the phase shifting reactor.

If the parallel reactor has a closed iron core, and is designed so that normally it operates with considerable saturation, then the voltage across X_P and C_P will remain almost constant with considerable fluctuation in line voltage or change in the reactance of the phase shifting reactor. Figure 9*b* is a vector diagram illustrating the voltage and current phase relations in this circuit.

As shown here, the loss component of current through X_{PS} determines the phase shift for a given value of reactance in X_{PS}. The reactive component of current in X_{PS} operates to maintain constant voltage across C_P and X_P. This reactive component is a balance between current taken by C_P and X_P which varies according to line voltage due to the fact that X_P is saturating. In practical operation this permits a 90° phase shift with no perceptible change in peak voltage output. The line voltage may likewise change 30% with only a 1% change in voltage across C_P and X_P.

Peaked-Wave-Transformer Excitation

The impulse produced by a conventional peaked wave transformer has the shape desired for ignitron excitation. Such a transformer, connected to block out or by-pass the negative peaks, is a satisfactory circuit. However, in a peaked wave transformer the impulse energy is stored periodically in the magnetic circuit and it is found that a transformer to produce impulses of the magnitudes required for ignitron excitation is prohibitively large.

Sine-Wave Phased-Back Excitation

Ignitors can be fired with 60 cycle sine waves. However, if the ignition is permitted to take place on the front of the wave from a circuit having capacity enough to supply the instantaneous power required by ignitors, the power loss is prohibitive. To avoid this high loss the voltage can be phased back or blocked by a thyratron, until a later point in the cycle where the follow current is much less. Such a circuit is shown in figure 10. In any event, the degree to which ignition can be phased back is limited and the minimum follow power attainable results in rather high excitation losses. Furthermore, the power consumption varies greatly with the angle of phase back so the range of grid control is very limited and the highest loss is at the minimum delay angle where rectifiers operate the majority of the time. Practically, control of rectifier voltage with this type of excitation requires that a phase shifter be placed in the power supply to the excitation circuit.

A modification of the circuit shown in figure 10 can be made by placing a single resistor in the neutral of the excitation transformer instead of the individual resistors in the ignitor leads. Such a resistor would cause the circuit to produce 60 degree pulses as in a six phase rectifier.

Multianode-Control Rectifier

The sine wave-phased back circuit can be modified as shown in figure 11, so so as to permit the use of a miniature multianode grid controlled rectifier. Since such a rectifier has a common cathode,

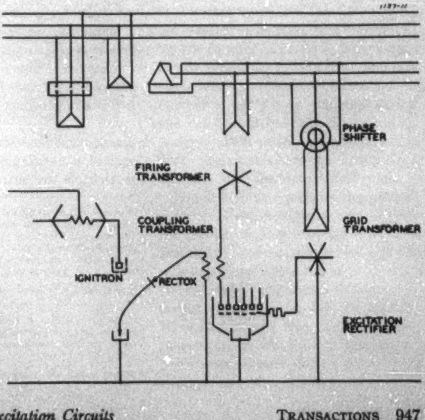

Figure 11. Ignitron rectifier circuit with miniature grid-controlled rectifier excitation

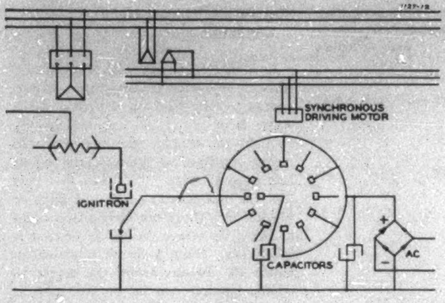

Figure 12. Rotating-commutator excitation system for ignitron rectifiers

coupling transformers are required in order to segregate the individual ignitor circuits.

The advantage of this circuit is that it retains low energy electronic control comparable to thyratron control, but eliminates the replaceable tubes. Its attractiveness is limited to pumped ignitrons where the addition of a small auxiliary pumped device involves little disadvantage. The range of grid control available with this circuit is limited, unless the entire excitation power is shifted, since, in common with the phased-back circuit, the excitation power varies widely with the phase back angle.

Rotating-Commutator Excitation

Figure 12 shows a system of excitation in which a rotating contact member is driven by a synchronous motor. As the moving contact passes under the brushes connected to the d.c. source, the capacitor is charged and when it passes under the brushes connected to the ignitors, the capacitor is discharged through the ignitor. Obviously, the capacitor could be connected to the stationary member and the ignitor contacts rotated if dictated by convenience. Control of voltage can be obtained either by means of rotating the stationary contact members or by any convenient means of shifting the phase position of the driving motor.

This system is most efficient and flexible as regards circuit constants, but it has the disadvantage of including a rotating member and sliding contacts with the resulting maintenance requirements.

Conclusions

In general, the development of the ignitron has progressed to a point where several circuits are available for excitation. These will provide positive and accurate ignition independent of load, and their attractiveness depends upon the application. Any of the circuits described in this paper which are in commercial use have a power consumption sufficiently small that the effect on overall efficiency is less than .1% for large units, and does not exceed .4% on units as small as 200 K.W.

The use of thyratrons in an excitation circuit provides a flexibility and speed of response that cannot be matched by any circuit using elements depending on mechanical movement or change of current in an inductive circuit, to provide control.

The saturating reactor excitation system, consisting entirely of static devices, by elimination of tube replacement appears to offer practical advantages for many applications.

When used with a phase shifting network, the saturating reactor system can be controlled with small power devices or compensating circuits, and has a speed of response adequate for most applications.

A Simple Method for Determination of Ratio Error and Phase Angle in Current Transformers

Correlation of Significant Constants of Current Transformers

E. C. WENTZ
ASSOCIATE AIEE

Synopsis: Up to the present time current transformer performance has been described by curves which show ratio error and phase angle over a range of current at various values of burden, (ohms) power factor, and frequency. The number of curves that are required to cover all possible conditions is so great as to render them, by their very bulk, practically useless. Another limitation is that they do not describe performance under transient conditions.

Performance of other types of transformers and certain other apparatus is invariably calculated from a few easily measured constants, according to simple standard formulas. Up to the present time, available methods for calculation of current transformer performance have had the disadvantage of either being difficult to use, or of depending on constants difficult to measure, or else they have not been sufficiently accurate for general use.

A method is described which depends on the following constants:

1. Open-circuit saturation curve measured in the usual way.
2. Secondary coil resistance.
3. Equivalent leakage reactance calculated from the voltage of an exploring coil enclosing the maximum value of leakage flux.

The method includes several important short cuts in the calculation which reduce the numerical work to a practical minimum. Curves are plotted which allow direct reading of the exact components of exciting current which cause ratio error and phase angle.

The objects of the paper are:

1. To present a practical method of calculation.
2. To establish constants (1), (2), and (3) as the fundamental quantities which determine real excellence of the transformer.

I. The Need for a Simple Method for Description of Current-Transformer Performance

THE conventional ratio and phase-angle curves for a current transformer are often inadequate for solution of a particular problem. Furthermore, the tests from which such curves are plotted are expensive, and the data are not available for many of the older transformers now in service.

A simple method for determining current transformer performance from a few easily measured constants (as power transformer performance is determined from copper and iron loss and impedance measurements) has been earnestly sought. This paper will present a method which the author believes to be the best so far proposed.

II. Theory of Current Transformation

The general principle of calculation of current transformer performance is very simple. The ampere turns in the secondary coil are less than those in the primary coil only because of the ampere turns lost in circulating flux in the core. Hence, we need only to calculate the ampere turns or magnetomotive force drop around the magnetic circuit.

However, on account of the leakage flux in the core, this is not as simple as it sounds. This leakage flux is principally the flux which passes between primary and secondary windings, and completes its path in the core outside the primary winding (figure 1). The current transformer is different from other transformers in that this leakage flux is relatively large, often larger than the working flux. This flux has been investigated experimentally[1] and theoretically,[2,3] but no method has been developed by which it can be exactly calculated. Furthermore, it is well known that it enters the core, not at one point, but all over the whole surface, so that it is not the same at any two points in the core

If any one of a number of approximate methods is used to calculate the leakage flux, the ampere turns to circulate it through the core can be calculated by dividing the core into a number of parts, assuming a constant equivalent flux in each part. This is the basis of the method described by Mr. Sinks,[3] and this method, although still not absolutely correct (its limitations are fully described by Mr. Sinks), is the most nearly correct method now available. Its real limitation is the great amount of numerical work involved.

III. Assumptions Which Simplify Calculation

Certain methods have been developed for simplifying this calculation. The most simple method, which does very well for ring type transformers, is to neglect the leakage flux altogether.[4] Another method assumes an experimentally determined flux, approximately related to an average value of leakage flux, to flow in the whole core.[5] These methods are not suitable for general use, because they do not use the real magnitude and distribution of the leakage flux.

IV. Combination of Best Features of All Methods

Giving first consideration to the fundamental soundness of the method, we can say that the method should—

1. Consider division of the core into several parts, as discussed in II with different leakage fluxes in the different parts.
2. Base the distribution of the leakage flux and the division of the core, on values of leakage flux actually existing in the core as measured by exploring coils (figure 2). The exploring coil can be simply ten turns of fine wire.

Giving second consideration to the aspects of economics and convenience, we can say that the method should not divide the core into more parts than is necessary for the required accuracy. Here a good deal of experience is required. Any particular division of the core into any finite number of parts is an empirical device, and can be justified only by general experience which shows that it works. The final result cannot be shown, in any rigorous way, to be the best possible result.

It will help to remember the primary objects of the investigation, and to make the division of the core accordingly. The first object is to calculate an error that is at least as large as the real error, to be on the safe side. The second is to get consistent results, to be able to compare transformers on a true basis. The first object can be obtained if the average flux values in each part of the core are taken to be sufficiently large, even if the

PRIMARY
SECONDARY
ASSUMED EQUIVALENT DISTRIBUTION
APPROXIMATE REAL DISTRIBUTION OF FLUX

Figure 1. The leakage flux passing in the space through and between coils completes its path through the core

The leakage flux is relatively large in a current transformer

core is not too well divided. The second object will be obtained if the flux measurements are made in the same way on all transformers of the same type.

Of course, we do not want to calculate an error too much larger than the true value. This is the disadvantage of not dividing the core at all, but considering the measured value of leakage flux to flow in the whole core; the calculated error will always be too large.

Division of the core into two parts, with the real leakage flux measured by exploring coils, is a compromise which the test results to be cited, and other tests, show to be suitable for general use with dry type transformers. This compromise is, however, definitely not fundamental; the general method to be described can be used with any desired division of core.

When the ratio error exceeds five per cent, the iron is usually working near saturation, and much of the leakage flux which is in the iron at normal flux densities leaves the core at the higher density and completes its path in the air leaving less flux in the core than would be expected. The result is that this method of calculation will give errors which are considerably too large when the error exceeds five per cent. As the method is conservative, it is still useful.

Actually less than the value of flux as measured by the exploring coil shown in figure 2 exists in practically all of the core. It is obviously conservative to assume that it exists in the half of the core which is outside the primary coil. Mr. Sinks has shown that the leakage flux at the center of the core inside the secondary is effectively reversed to the leakage flux in part of the core just outside the secondary. A reasonable assumption, confirmed by tests, is that the average effective value of leakage flux in the inside half of the core is zero, and that the only flux to be considered is the working flux.

V. Simplification of Numerical Work

The proposed method of determining the leakage flux and its distribution does not solve a real difficulty attending the problem—the amount of numerical work for a solution.

Several short cuts have been worked out which do not detract from the accuracy of the calculation. These are:

1. Substitution of equivalent reactance for the leakage flux. It can be shown (appendix I) that the transformer with magnetic circuit divided into two parts, one with, one without, leakage flux, can be represented by the equivalent circuit of figure 4, where the reactance X_L corresponds to the leakage flux and can be determined from the exploring coil voltage at normal current by—(see appendix II)

$$X_L = \sqrt{\left(\frac{N_s}{N_x}\frac{E_x}{I_s}\right)^2 - R_s^2}$$

I_s = secondary current
R_s = secondary coil resistance
N_s, N_x = number of turns in the secondary and exploring coils, respectively
E_x = induced voltage in the exploring coil

(2). When the transformer is considered as the equivalent circuit in figure 4, the problem of calculating primary (input) current from the secondary (output) current is simply vector algebra. The fact that we have limited the method to five per cent ratio error (approximately five per cent total exciting current maximum) justifies the assumption that the voltage drop in X_L is not $(I_s - I_{e1})X_L$ (see figure 4) but $I_s X_L$, and the voltage on the number 2 exciting branch is $I_s(Z_b + R_s + X_L)$ (adding vectorially). The calculation of performance is then exactly as if the two exciting branches were two separate current transformers, one with burden $Z_b + R_s$, the other with burden $Z_b + R_s + X_L$, and the ratio and phase-angle errors will be the sum of the errors of the two.

3. It is well known[7] that the component of exciting current which produces ratio error is:

$F \cos \theta + M \sin \theta$
F, M = watt reactive components of exciting current, respectively
$\cos \theta$ = burden power factor

This value, added to the secondary current, gives the primary current reversed. The formula is:

$$\text{per cent ratio: per cent turns ratio} + \frac{100\,(F \cos \theta + M \sin \theta)}{I_s}$$

I_s = secondary current

Calculating the value of $F \cos \theta + M \sin \theta$ from the ordinary open-circuit secondary saturation and power factor curves is not difficult, but calculation of a number of points is tedious. Now the ordinary saturation curve is plotted between exciting current, which is $\sqrt{F^2 + M^2}$, and secondary voltage. It is not much more difficult to plot $F \cos \theta + M \times \sin \theta$ for a number of values of $\cos \theta$, instead of $\sqrt{F^2 + M^2}$, and the desired value can then be read directly.

$$\text{Phase angle} = \frac{3438}{I_s}\,(M \cos \theta - F \sin \theta)$$

The phase-angle component is $M \cos \theta - F \sin \theta$, and a similar set of curves can be plotted for this value.

Figure 5 is an example of such a set of curves for one transformer and figure 7 is a set of $F \cos \theta + M \sin \theta$ curves for a different transformer. The log-log co-ordinates of figure 5 are more useful if the lower range of the curves is important. This idea was originated by A. M. Wiggins.[6]

The data needed for calculating performance then are:

(1). Saturation curves of the form $F \times \cos \theta + M \sin \theta$ and $M \cos \theta - F \sin \theta$ plotted against secondary voltage, for a number of values of $\cos \theta$ (see figure 5).

(2). Secondary winding resistance.

(3). Leakage reactance X_L measured according to appendix II.

The procedure is:

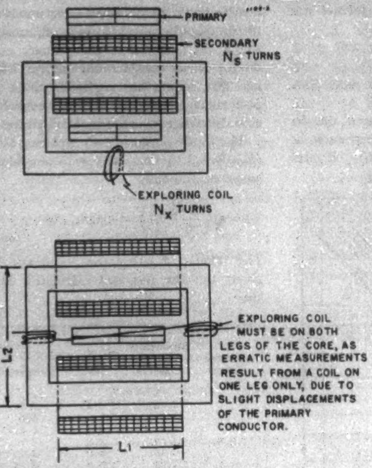
(1). Given burden and power factor, determine the total burden on the right hand exciting branch of figure 4. (Burden+secondary resistance $= Z_1$.) Also determine the sum of this burden$+X_L$, which is the burden on the left hand exciting branch. $Z_1 + X_L = Z_2$. (Vectorial addition.)

(2). From these two values of burden in ohms and the secondary current, calculate the voltages on the two exciting impedances.

$E_1 = I_s Z_1$
$E_2 = I_s Z_2$

(3). From the $F \cos \theta + M \sin \theta$ curves, read values for E_1 and E_2 and find per cent ratio by—

$$\text{per cent ratio} = \text{per cent turns ratio} + \frac{100}{2} \times \left[\frac{(F \cos \theta + M \sin \theta)_1}{I_s} + \frac{(F \cos \theta + M \sin \theta)_2}{I_s}\right]$$



PRIMARY
SECONDARY
N_S TURNS

N_X TURNS
EXPLORING COIL MUST BE ON BOTH LEGS OF THE CORE, AS ERRATIC MEASUREMENTS RESULT FROM A COIL ON ONE LEG ONLY, DUE TO SLIGHT DISPLACEMENTS OF THE PRIMARY CONDUCTOR.
L2
L1

Figure 2. The most direct and simple as well as the most nearly correct method for determination of leakage flux is measurement by exploring coils

The lengths $L1$ and $L2$ represent relative (not absolute) lengths of the part of the magnetic circuit which can be considered to carry no leakage flux and all the leakage flux, respectively, in a through-type transformer

The subscripts 1, 2, refer to the two parts of the core; the division by 2 takes account of the fact that each component is for only half of the core, whereas the saturation curves are for the whole core. It will be noted that the exact turns ratio must be known. This ratio is often difficult to measure, but the manufacturer can always supply it. It may also be difficult to place the exploring coil on a transformer. This also is easy for the manufacturer, however. General use of this method will probably depend on the manufacturer's measurements of exact turn ratio and leakage flux.

$$\text{Phase-angle minutes}=\frac{3{,}438}{2}\times\left[\frac{(M\sin\theta-F\cos\theta)_1}{I_s}+\frac{(M\cos\theta-F\sin\theta)_2}{I_s}\right]$$

VI. Comparison of Tests and Calculations

The constants which determine the performance of the transformer at a given frequency are:

(1). The secondary coil resistance.

(2). The secondary leakage reactance X_L measured according to appendix II.

(3). The $F\cos\theta+M\sin\theta$ and $M\cos\theta-F\sin\theta$ curves for exciting current plotted against secondary voltage.

(4). The burden.

(5). The secondary current.

The fact that this method gives correct results for ring type transformers, in which there is no leakage flux, has been amply demonstrated.

The method has been demonstrated on several wound type transformers, and the constants for one wound type and one through type transformer will be given, together with calculated and measured results.

(a) Wound-Type Transformer

Secondary coil resistance:

0.3 ohm. (R_s)

Secondary leakage reactance:

Exploring coil voltage E_x 0.148 in 10 turns ($N_x=10$)
At I_s = secondary current = 5 amperes
N_s = secondary coil turns = 239
From equation 7, appendix I

$$X=\sqrt{\left(\frac{0.148\times239^2}{5\times10}\right)-0.31^2}=0.638\text{ ohm}$$

The $F\cos\theta+M\sin\theta$ and $M\cos\theta-F\times\sin\theta$ curves are given in figure 5.

The calculation of a given point is as follows:

Secondary current = 5 amperes
Burden = 0.6 ohm, 90 per cent power factor = $0.54+j\,0.262$
Add R_s (secondary coil = 0.31
(Z_1 = 0.89 ohm, 96 per cent power factor) Z_1 = $0.85+j\,0.262$
Burden voltage $E_1=4.45$
Add X_L = $j\,0.638$
Z_2 = 1.24 ohms 69 per cent power factor $0.85\ \ j\,0.9$
Burden voltage $E_2=6.2$
From figure 5, at $E_1=4.45$, $(F\cos\theta+M\sin\theta)_1=0.0133$
at $E_2=6.2$, $(F\cos\theta+M\sin\theta)_2=0.0229$

$$\text{Per cent ratio}=\left\{\begin{array}{l}\text{per cent turns ratio}=99.584+\\ \dfrac{100}{2}\ \dfrac{(0.0133+0.0229)}{5}=\dfrac{0.362}{99.946}\end{array}\right.$$

Test value = 99.89

The curves of figure 6 were calculated in the same way, and one who desires to may check them very rapidly by the use of tabular calculations.

(b) Through-Type (Two-Coil) Transformer

Good results are generally obtained by dividing the core into two equal parts, in the case of a wound type current transformer, but the division should not be made quite this arbitrarily for a through type current transformer. If the length of magnetic circuit not enclosed by the coils is taken as the part carrying leakage flux, and the axial length of the coil is taken as the part not carrying leakage flux, better results are generally obtained. These two lengths are, more often than not, nearly equal, so that the final division is usually not far from division into two equal parts, but some designs are made with unusually long yokes which carry the leakage flux, and account should be taken of their length. The lengths of these parts of the circuit are usually easily measured, according to figure 2.

The particular design in question was such that the core could be considered to be divided into equal parts.

MAGNETIZING BRANCH REPRESENTING CENTER ELEMENT OF CORE

Figure 3. The flux at the center of the core inside the secondary coil is actually less than enough to generate the total burden voltage, because the "leakage" flux passing through the body of the secondary coil actually links some of the secondary turns and induces a part of the secondary voltage

This real reduction of flux in the center element of core can be represented exactly by a negative series reactance or a capacitor C

Each successive element of the core, starting from the center element, carries a greater part of the real leakage flux, represented by added series reactances, and the network is an accurate equivalent

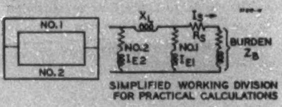

Figure 4. A practical working equivalent for figure 3 is the two-branched network

The curves for this transformer are given in figure 7.

The secondary resistance was 0.345 ohm. (R_s)

The secondary turns (N_s) were 280; ratio 1,400/5 amperes.

Two exploring coils were used, one on each yoke of the core, ten turns each, in series as in figure 2 ($N_x=20$). Erratic results would be obtained from measurements on only one exploring coil, as only slight displacement of the primary conductor causes considerable shifts in leakage flux, which has negligible effect on performance, but which causes considerable difference in individual coil voltages.

The total voltage of two exploring coils (E_x) was 2.15 volts at $I_s=15$ secondary amperes, and thus

$$X_L=\sqrt{\left(\frac{280}{20}\,\frac{2.15}{15}\right)^2-0.345^2}=1.98=2.0 \text{ ohms}$$

The details of calculation need not be given, but the test and calculated data are—

Burden Ohms	Secondary Current Amperes	Per Cent Ratio Error	
		Test	Calculated
1.0	50	0.5	0.59
	75	3.0	4.5
2.0	25	0.1	0.28
	50	3.3	3.1
	55	4.2	4.7
4.0	25	0.7	0.75
	35	5.5	5.4

At larger currents, where errors are much larger, the test values do not agree with calculation.

This design is typical of two-coil through type transformers, and the two-ohm equivalent internal reactance is also typical for this ratio. The burden may often be less than the equivalent internal impedance, so that the performance of the transformer may sometimes not be much affected by burden.

If the ratio is higher than 1,400/5 the internal impedance will be higher, increasing approximately as the square of the ratio, and if the core section is increased the internal impedance will increase almost in proportion. The result is that a two-coil through type current transformer of conventional design will not perform well at primary currents much above 25,000 primary amperes, regardless of the amount of iron in the core.

VII. Other Uses for Saturation Curves and Secondary-Coil Resistance Data

(1) Transient Performance

The use of the secondary coil resistance and saturation curve for determining per-

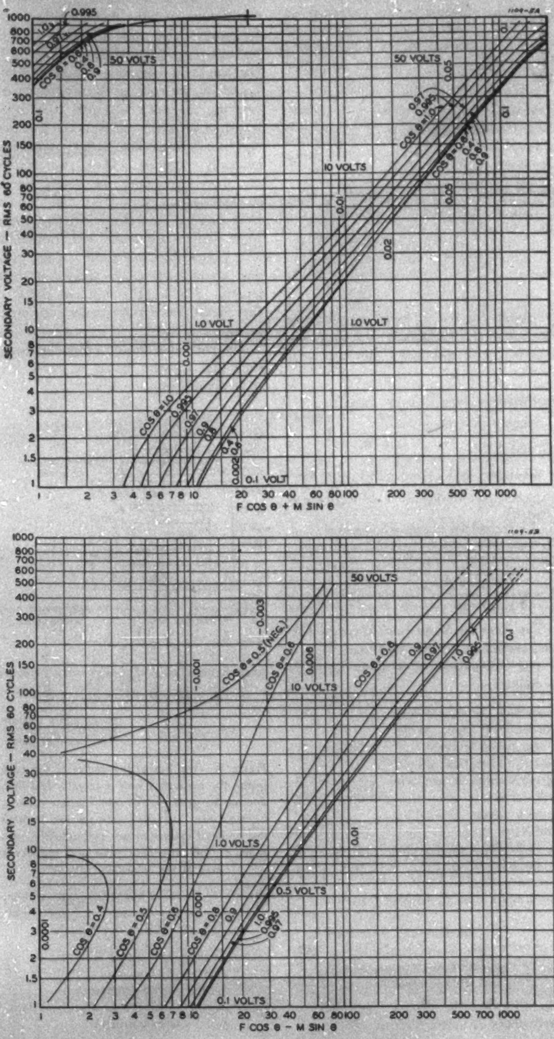

Figure 5. F cos θ+M sin θ and M cos θ − F sin θ curves for a typical transformer

These are calculated from the watt (*F*) and reactance (*M*) components of the open-circuit secondary saturation curve. Cos θ is the burden power factor formance at transient currents has been fully described in previous papers.[8,9]

(2) Parallel Connection

When current transformers are connected in parallel, the primary current of one of the transformers may be very low, or even zero. If it is very low, while the burden voltage is relatively high because of current supplied by the other transformers in parallel, the effective burden impedance (:volts/current) is very high, higher than any usual burden, and the performance of the current transformer at such a burden will seldom be given by the standard performance curves. The performance can then easily be determined by the method given.

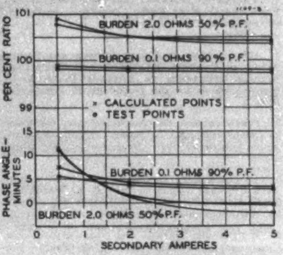

Figure 6. Calculation versus test

Wound-type current transformer calculated from figure 5, and secondary resistance = 0.31, leakage reactance 0.638

If the primary current is zero (primary circuit open) the exciting current drawn by the dead current transformer can be read from the same saturation curve, and its effect on the current supplied to the burden calculated in the same direct way.

VIII. Constants Determining the Excellence of a Current Transformer

The real excellence of a current transformer is determined by examination of ratio and phase-angle data. However, it is not economical, as has been pointed out, to measure ratio and phase angle at every possible condition, and comparison of overcurrent data on two current transformers is usually awkward, and often inconclusive.

When current transformers operate relays, ratio errors of less than five per cent are usually of no consequence. The power factor of the total burden with the usual relays will be in the neighborhood of 60 per cent. If the primary current is the common figure of 10 times normal, or 50 amperes secondary current, $F \cos \theta + M \sin \theta$ must be 2.5 to produce an error of 5 per cent. Then the magnitude of the voltage, according to the $F \cos \theta + M \sin \theta$ curves, at which $F \cos \theta + M \sin \theta$ will be 2.5 is one general measure of the excellence of the current transformer (see figure 5).

The resistance of the secondary winding and the equivalent value of X_L determine how much must be added to the connected burden to determine how much burden the transformer has to carry. Hence these figures also are measures of the excellence of the current transformer.

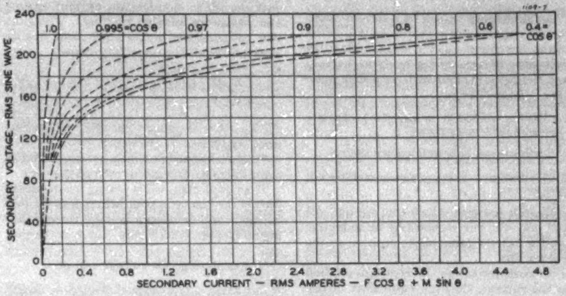

Figure 7. F cos θ+M sin θ curve for a through-type current transformer

$F \cos \theta + M \sin \theta$ is the component of exciting current which must be added to the secondary output current to get primary input current reversed (1/1 ratio basis). Example: burden four ohms at 80 per cent power factor, secondary current 50 amperes, exciting current (from curve) at $4 \times 50 = 200$ volts = 1.8 amperes. Primary current reversed = 51.8, ratio = 100 (51.8/50) = 103.6 per cent

Thus two indices of excellence which can be readily compared are:

(1). Secondary voltage at which $F \cos \theta + M \sin \theta$ for 60 per cent power factor is 2.5.

(2). Internal resistance and reactance.

IX. Conclusions

A simple method for calculation of current transformer performance has been developed. It is not new in fundamental principles, but it is an improvement and simplification of the most accurate existing method.[3]

It is more direct in its use of leakage flux; it uses a real measured value in its calculations; furthermore, the measurement of flux is easily done with exploring coils without other special equipment. The exploring coil can be threaded through the space between core and coil in many transformers, especially older models.

The method is flexible. If further experience shows the necessity for further division of the core, two sets of exploring coils can be used with a division of the core into three parts. It can be made to be as accurate as desired.

It proposes a simple equivalent circuit for calculations which includes an internal reactance. This simplifies the calculation, and isolates and defines a constant of the transformer: the equivalent internal reactance of a current transformer is that reactance which as burden would require an additional flux equal to the maximum measurable value of leakage flux in the core. A formula for the reactance in turns of exploring coil measurements is included.

The errors in the method are on the conservative side. The real exciting current is less than the calculated value, and at the higher values, corresponding to saturation of the core, where the ratio error usually exceeds five per cent, the calculated ratio error is usually much too high. Thus, the method is useful even where it is not too accurate.

Curves are proposed for simplification of the vector algebra. This expedient is of great value when many calculations are to be made. However, this part of the method is not essential. Any correct method of vectorially adding exciting current to secondary current can be used.

The performance under transient conditions, at unusual burdens or currents (including performance of parallel transformers) can all be determined from the characteristics listed above, using available methods[8,9] for transient performance, and the method described above for performance at unusual burdens or currents.

The performance of a current transformer is shown to depend on a few simple constants of the transformer:

(1). Internal resistance

(2). Internal reactance as defined

(3). Open-circuit saturation curve

Comparison of (1), (2), and one point on curve (3) allows formation of judgment about the relative excellence of transformers.

Appendix I. Equivalent Circuit for Current Transformers

An inductance burden on a current transformer requires a voltage 90 degrees ahead of the current, and as the flux to induce the voltage is, in turn, 90 degrees from the voltage, the flux is in phase with the primary current. So we may say:

1. The flux required by an inductive burden is in phase with the primary current.

Furthermore, it is well known that—

2. The leakage flux is also in phase with the primary current.

We can combine statements (1) and (2) and say—the flux required by an inductive burden has the same phase position as the leakage flux.

As both fluxes are directly proportional to the current, they are equivalent fluxes, and the leakage flux can be represented, if desired, by an equivalent inductance in the burden.

As shown by Mr. Sinks,[3] the leakage flux at the center of the core inside the secondary coil has, in effect, a negative value, but has higher values in each succeeding element of the core. For purposes of analysis, we can separate the core elements and represent each one by an equivalent exciting branch. The fact that each element carries a certain leakage flux can be represented by an equivalent inductance in series with the current circuit, as in figure 3. The fact that the leakage flux at the center corresponds to a negative inductive reactance is represented by a capacitance in series with the first branch.

For practical work in which the core is divided into only two parts, one of which is assumed to carry no leakage flux, the circuit takes the simpler form shown in figure 4, in which the series equivalent inductance is determined according to appendix II.

Appendix II. Exploring Coil for Flux Determination

If the secondary winding of a current transformer is short-circuited, the total real linkages of flux with the secondary coil are just enough to circulate the current against the resistance of the winding. This flux can be calculated as an equivalent flux ϕ_s which links all the secondary turns.

$$\phi_s = \frac{I_s R_s 10^8}{4.44 f N_s} \qquad (1)$$

I_s, R_s, N_s = secondary current, coil resistance, and turns, respectively.

This amount of flux may be considered as a working flux flowing all around the core.

If an exploring coil is placed on the outer part of the core at a point where leakage flux exists, it will develop a voltage corresponding to ϕ_s plus (vectorially) the leakage flux ϕ_L.

The exploring coil voltage will be—

$$E_x = 4.44(\phi_s + j\phi_L) f N_x 10^{-8} \qquad (2)$$

j expresses the fact that the vector ϕ_L is at right angles to the vector ϕ_s. In absolute values,

$$\left(\frac{E_x 10^8}{4.44 f N_x}\right)^2 = \sqrt{\phi_s^2 + \phi_L^2} \qquad (3)$$

$$\phi_L = \sqrt{\left(\frac{E_x 10^8}{4.44 f N_x}\right)^2 - \phi_s^2} \qquad (4)$$

$$\phi_L = \sqrt{\left(\frac{E}{N_x}\right)^2 - \left(\frac{I_s R_s}{N_s}\right)^2}\ \frac{10^8}{4.44 f} \qquad (5)$$

The leakage flux ϕ_L can be expressed as an equivalent reactance referred to the secondary winding of N_s turns and peak current $\sqrt{2}\, I_s$

$$X_L = \frac{2\pi f N_s \phi_L 10^{-8}}{\sqrt{2} I_s}$$

$$= \frac{2\pi f}{\sqrt{2}}\ \frac{10^8}{4.44 f} \sqrt{\left(\frac{N_s}{N_x}\ \frac{E_x}{I_s}\right)^2 - R_s^2}\ 10^{-8} \qquad (6)$$

$$X_L = \sqrt{\left(\frac{N_s}{N_x}\ \frac{E_x}{I_s}\right)^2 - R_s^2} \qquad (7)$$

Symmetrical Nomenclature of Three-Phase Circuits

BRYCE BRADY
MEMBER AIEE

Synopsis: Two methods of identifying three-phase conductors, voltages, and currents are in general use today. One method, used extensively on power systems and based on 30° voltage relations, is called "standard" nomenclature.[1,2,3] The other method, used frequently for analytical purposes and based on 90° voltage relations, is called "symmetrical" nomenclature.[4]

The following advantages of the symmetrical plan are discussed:

1. It is easier to use.
2. It identifies single-phase currents.
3. It requires fewer angles.
4. It is universal.
5. It is symmetrical.

Introduction

THE transformations most commonly used on three-phase power systems are the delta-Y and Y-delta connections which always introduce voltage phase shifts in the circuit, and the delta-delta and Y-Y connections which sometimes do. It is important to operating and design engineers that the voltage phase position of each terminal and conductor be identified by some arbitrarily adopted system of nomenclature. Such identification becomes more and more necessary as the number of successive transformations is increased.

The two nomenclature methods in general use are contrasted in figure 1 for a delta-Y transformation. Corresponding symbols are assigned to conductor-to-neutral voltages which differ by 90° in the symmetrical plan, and to voltages which differ by 30° in the standard plan. Both methods are expanded in figure 2 to provide a comparison with several variations of delta-Y and Y-delta connections. The two plans are identical with reference to delta-delta and Y-Y transformations, so these are omitted for the sake of brevity. Balanced voltage with counterclockwise (*ABC*) sequence is assumed throughout.

Ease of Application

A simple *ABC* rule facilitates the application of symmetrical nomenclature to all delta-Y and Y-delta transformer connections. For example in figure 2*a*, Y conductor *A* always corresponds with delta conductors *B* and *C* regardless of whether the connection is delta-Y or Y-delta, or whether the polarity is additive or subtractive, or whether the voltage displacement is lagging or leading. There is no exception to this easily remembered rule.

The rule for application of standard nomenclature is more complicated as illustrated in figure 2*b*, for sometimes Y conductor *B* and sometimes Y conductor *C*, corresponds with delta conductors *B* and *C*. This variability not only makes the rule more difficult to remember and use, but it renders standard nomenclature incapable of identifying single-phase fault currents.

Fault-Current Identification

This same *ABC* rule positively identifies the flow of single-phase fault or load current through delta-Y and Y-delta transformations, if symmetrical nomenclature is used. For example in figure 3*a*, conductor *A* always supplies 100% current to a fault between conductors *B* and *C* on the load side of the transformation. Conversely, conductors *B* and *C* always supply 100% current if the fault occurs on conductor *A*. There is no exception to this simple rule.

Figure 3*b* illustrates the fact that such identification is impossible without supplementary data if standard nomenclature is used, for 100% current is sometimes supplied by conductor *B*, and sometimes by conductor *C*, through such transformations to single-phase faults between conductors *B* and *C*.

This failure of standard nomenclature to provide definite current identification is a major limitation of the method which cannot be evaded by standardization of connections, for both lagging and leading connections are necessary in a series of transformations to cancel voltage shifts and to obtain zero voltage displacement.

Fewer Angles

If either lagging or leading voltage displacement is allowed to accumulate in a series of transformations, only four kinds of three-phase voltages can result, such that parallel operation between circuits with different kinds is impossible. These four kinds are interpreted quite logically by the symmetrical plan to be the four multiples of 90°, as illustrated in figure 4*a*.

In such a series, the displacement be-

tween the same four voltage diagrams is interpreted at 30° intervals by the standard plan to present the illusion of twelve phase positions, as illustrated in figure 4*b*. The eight additional angles do not describe new phase positions, but merely represent rearrangements of symbols on the original four voltage diagrams. The use of such electrically duplicate angles, differing by 120° multiples, provides opportunity for confusion and error, and also destroys the ability of standard nomenclature to identify conductors with voltages that are in phase.

Universality

Situations frequently occur in practical applications where standard nomenclature fails to identify the conductors which must be interconnected for parallel operation. The connection diagram in figure 5*b* illustrates such a case where 4 kv conductor *A* originating in one substation must be connected to 4 kv conductor *B* originating in another substation, *B* to *C*, and *C* to *A*. Although all connections in the diagram are uniform and correct, the standard method of nomenclature causes confusion in the identification of 4 kv bus conductors. Circuit connections of this nature can occur in actual practice as a result of placing the 66 kv transformers back to back to reduce substation costs, or as a result of attempting to maintain uniform geographical phase sequence in all substations, such as phase sequence

Figure 5. The symmetrical plan is universal

ABC from north to south and from east to west. Such situations usually cannot be tolerated for safety, relaying, and other reasons and must be carefully avoided if standard nomenclature is used.

The symmetrical method does not have such limitations for conductors with inphase voltages are always identified by corresponding symbols. For example in figure 5*a*, 4 kv conductor *A* originating in one substation is connected to 4 kv conductor *A* from the other substation, *B* to *B*, and *C* to *C*.

Symmetrical nomenclature is universal to the extent that it can always be applied without confusion to all conductors of a three-phase network, regardless of the sequences of delta and Y connections which may be used, and regardless of the number of interconnections and loops which may be added. It is the only nomenclature plan by which all in-phase delta and Y voltages on a three-phase network of unlimited complexity can be identified by the same symbol.

Symmetry

The symmetrical plan is based on the interpretation that all delta-Y and Y-delta transformations cause either +90° or −90° voltage displacement, and that all delta-delta and Y-Y transformations cause either 0° or 180° displacement. The symmetry of this classification is contrasted in figure 6 with the lack of symmetry of the standard classification.

The mathematical advantage of using such diametrically opposed groups is apparent in the treatment of polarity reversal or the equivalent connection reversal, for according to the symmetrical plan the effect of such reversal is always interpreted to be 180° displacement of voltage. If standard nomenclature is used, it is necessary to resort to the odd interpretation that such reversal causes 180° displacement in case the connection is delta-delta or Y-Y, but only 60° displacement if the connection is delta-Y or Y-delta. This anomaly results from the use of 30° angles to describe voltage phase shifts, and is the cause of many confusing situations in power transmission and distribution work.

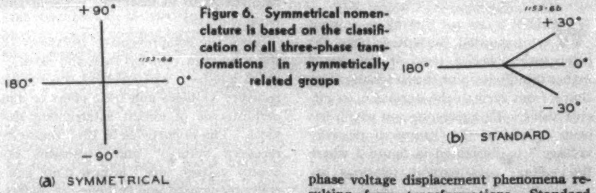

Figure 6. Symmetrical nomenclature is based on the classification of all three-phase transformations in symmetrically related groups

The use of operator *j* is well developed in electrical engineering mathematics and fits perfectly with the symmetrical interpretation that the three-phase voltage displacement resulting from transformations is always a multiple of 90°. Change from standard to symmetrical nomenclature is accomplished by merely interchanging symbols on conductors and vector-diagrams after delta-Y and Y-delta transformations. It involves no change after delta-delta and Y-Y transformations; no change in physical connections; no change in vector diagram procedures; and no change in the use of arrows to identify instantaneous values.

Conclusions

The symmetrical plan of identifying three-phase conductors, voltages, and currents is worthy of more extensive use today and in the future because of the following advantages over the standard plan:

1. It is easier to use because symbols are applied by means of simpler rules.

2. It identifies the conductors which supply current through delta-Y and Y-delta transformations to single-phase faults—an impossibility by means of standard nomenclature.

3. It requires only four angles—the four multiples of 90°—to interpret all three-phase voltage displacement phenomena resulting from transformations. Standard nomenclature requires twelve angles—the twelve multiples of 30°—to accomplish the same purpose.

4. It is universal; it can be applied to transmission-distribution systems with unlimited delta and Y sequences and identify the conductors which must be interconnected for parallel operation. The standard plan sometimes fails to provide correct identification.

5. Mathematical advantages result from its perfect symmetry and the exclusive use of 90° multiples.

The Recovery-Voltage Analyzer for Determination of Circuit Recovery Characteristics

G. W. DUNLAP
ASSOCIATE AIEE

Synopsis: Widespread interest in transient recovery voltage phenomena has led to the development of a device for determining the recovery characteristics of circuits and apparatus. The problem was solved by making use of the multiple surge testing technique which, in turn, involves the use of a low voltage repeating type surge generator. This paper describes the method and necessary equipment and indicates the range of conditions to which they may be applied. Demonstration tests on miniature and full scale circuits are also shown.

WHEN a current flowing in a circuit is interrupted, the voltage across the interrupting device rises or "recovers" rather rapidly in some characteristic wave shape from zero to the normal open circuit value. This phenomenon which has been defined as the "transient recovery voltage"[7] is illustrated in figure 1 where the voltage and current relations are shown for the application and clearing of a fault on a hypothetical circuit. The characteristic wave shape is dependent on the connected circuit and may consist of an oscillation at one or more frequencies corresponding to natural frequencies of various parts of the circuit.

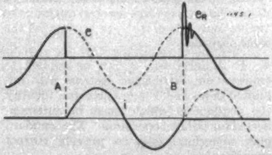

Figure 1. Diagram showing appearance of recovery voltage upon interruption of short-circuit current

e—System voltage
e_R—Recovery voltage
i—Short-circuit current
A—Point of fault application
B—Point of current interruption

The circuit interrupting device in performing its function of opening the circuit must contend with this voltage rise and must introduce insulation strength at a rate adequate to meet the stress of the rising voltage.

Since the comprehensive treatment of the subject in 1931 by Park and Skeats,[1] much has been written[2,3,4,5,6] concerning recovery voltages and their effect on the performance of circuit interrupting devices. The importance of the "transient recovery voltage" and "transient recovery voltage rate"[7] is now quite generally recognized and cathode-ray oscillograph measurements of these quantities are usually considered as part of standard test procedure for circuit breakers and other interrupting devices. Such measurements, though they involve expensive and time-consuming tests, are highly satisfactory and have proven of great value in the development work which has brought power circuit breakers to the present high level of performance.

Frequently, however, it is desirable to know the transient recovery voltage characteristics of a circuit where it is not practical to make interruption tests or cathode-ray oscillograph measurements, or where a breaker is not yet installed. Heretofore, the transient recovery voltage of the circuit was calculated by methods described elsewhere,[1,6,7] or it was sometimes possible to set up and analyze the circuit in miniature.[8,9,10] Such methods are dependent on a knowledge of the constants of the circuit in question. The accuracy of results is limited by the precision of this knowledge which involves many values of bushing and bus capacitance that in general can only be approximated.

By application of the multiple surge testing technique to the problem, a device known as the recovery voltage analyzer was developed. This analyzer permits the direct observation and measurement of the transient recovery voltage without full power interruption tests.

Technique

The multiple surge testing technique was developed as an adjunct to high-voltage impulse testing and the oscillograph electric transient analyzer[11,12] was built to utilize this method in the study of surge performance of a wide variety of apparatus. To briefly review this technique, it consists of the application to a test piece of a succession of low-voltage surges of controlled shape. In precise time coordination with these surges there is produced a series of sweep impulses for a cathode-ray oscillograph. When these voltages are put on the proper deflection plates of the cathode-ray tube, the successive surges superimpose on the tube screen and appear as a standing wave which may be viewed, traced, or photographed. In this way high-speed transient phenomena may be studied with the same facility had in reading steady state conditions with an ordinary voltmeter or ammeter.

Since the transient recovery voltage is also this type of phenomenon, the application of multiple surge testing to the problem was a logical step. This application was developed along two lines. The resulting methods will be distinguished by reference to them as the "substitution method" and the "current injection method" respectively.

Paper 41-145, recommended by the AIEE committee on protective devices, and presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941. Manuscript submitted April 12, 1941; made available for preprinting July 16, 1941.

G. W. DUNLAP is with the general engineering laboratory of General Electric Company, Schenectady, N. Y.

The author expresses his thanks to C. M. Foust for his many suggestions and guidance and to G. F. Davis for his cooperation in the study of switchgear testing circuits.

1. For all numbered references, see list at end of paper.

a. SUBSTITUTION METHOD

The substitution method was based on the idea of using the oscillograph electric transient analyzer to determine the constants of an unknown circuit or alternatively the constants of a simplified equivalent circuit. From these constants the transient recovery voltage could be calculated or read from curves of the type proposed by Boehne.[6] The justification of the method lies in the similarity of response to an applied voltage surge, of electrically equivalent circuits; and this was demonstrated by showing the transient responses of Boehne's circuits[6] to be identical for a wide range of applied voltage waves. Further demonstration was made by showing for the same wide range of waves that a full size power testing circuit with known constants behaved the same as a simplified equivalent circuit built up in the laboratory from lumped constants.

This method proved to be workable especially where the constants of a circuit are desired as in setting up a miniature representation of a system. However, it was less convenient than the current injection method for general usage.

b. CURRENT-INJECTION METHOD

This method has the advantage that the transient recovery voltage is shown as an oscillogram of the same type as that obtained by high-speed cathode-ray oscillography in connection with interruption tests. The usual measurements of frequency, amplitude, and rate of rise may be made directly from this oscillogram in the accepted manner. In addition the validity of the method is immediately apparent and may be readily demonstrated by mathematical analysis.

The method utilizes the device ordinarily employed in calculations involving current interruption and demonstrated elsewhere[1,6,14]; i.e., a current wave of the same shape as that which is considered as being interrupted is injected into the circuit under study. The resultant voltage is identical with that which would appear on actual interruption, and is therefore the recovery voltage. If interruption of an alternating current at current zero is assumed, the injected current must be of sinusoidal form. However, for the time interval during which the transient recovery voltage is of interest, a sine wave is essentially a straight line so the injected current may be of the form $i=\text{constant}\times\text{time}$. Off-zero interruption or interruption of d-c may also be simulated as will be described later; but the "ideal" interruption case is the most basic condition and the one on which most circuits will be comparable. This case will be considered in some detail.

A current of the desired linear form may be obtained by connecting a source of constant voltage to a linear inductance. Practically this is done by discharging the surge generator capacitance of an oscillograph electric transient analyzer through a suitable inductance. Of course when this arrangement is used to control the current applied to a test circuit the inductance must be sufficiently large in relation to the load so that there will be negligible distortion of the current wave.

Actually the problem was not as simple as it would appear. The inductance called for in the first design turned out to be too large and heavy for a portable equipment. It developed that a coil could not be built with low enough distributed capacitance to prevent the passage of an initial capacitance component of current which would appear as a "kick" at the beginning of the current wave. It was necessary to resort to a transformer in which the inductance could be utilized as before while the series capacitance path was virtually eliminated by electrostatically shielding the primary from the secondary. The same solution to the inductance problem was reached in England by Messrs. Trencham and Wilkinson[13,14] who applied their version of the oscillograph electric transient analyzer to the study of transient recovery voltages.

Further details of technique will become apparent as the various units of the recovery voltage analyzer are described.

Equipment

The present developmental model of the recovery voltage analyzer is shown in figure 2 and the several parts are described below.

a. MULTIPLE-SURGE GENERATOR

This unit is a simplified oscillograph electric transient analyzer[11,12] The actual circuit used is shown inside the dashed lines in figure 3. Briefly its function is the generation of a succession of surges, the shape of which will depend on the elements connected to the terminal marked "surge." Synchronized with the appearance of these surges there are available at the terminals indicated, impulses for initiating the cathode-ray beam and for sweeping the beam across the screen at a predetermined speed.

To give this result the circuit operates as follows: Thyratron T_1 is fired once every cycle of supply voltage by a peaking transformer connected to its grid. This provides a series of positive impulses at the "trip" terminal to initiate the cathode-ray beam and at the grid of thyratron T_3 to trip the surge in synchronism with the sweep voltage produced by the current flowing through the variable resistance R and the capacitor C_2 during the conduction period of T_1. The series

of surges is produced by the firing of thyratron T_1 which discharges the main capacitance C_1 through the circuit connected to the "surge" terminal. C_1 is charged through rectifier T_2 on each negative half cycle preceding the firing of T_1. Thus surges with synchronized beam control and sweep impulses are produced sixty times per second. This gives on the screen of the cathode-ray tube a stationary image of sufficient steadiness and brightness for viewing or photographing over the full range of sweep speeds giving sweep times of from 5 to 1,000 microseconds.

b. Multiple-Surge Transformer

The transformer is actually a set of interchangeable iron cored coils which viewed from the load side give a range of inductances from 60 millihenries to 4.5 henries. Each primary coil is electrostatically shielded by complete enclosure in a solid copper can with a gap between overlapping ends to avoid a short circuited turn. Experience showed that the shielding had to be very carefully designed to completely eliminate the objectionable "kick" mentioned before.

The function of this unit is the shaping of the wave to give the desired output of uniformly rising current surges. When the transformer is connected to the multiple surge generator as shown in figure 3, the repeated surges are discharged through the primary winding. Since for the time increments involved, the voltage applied to the primary is essentially constant, and since the transformer is operated well below saturation, the current flowing in the secondary is for the period of interest of the form $i = \text{constant} \times$ time. If the circuit to be measured is connected across the secondary, the current, controlled in form for all practical purposes by the transformer alone, will flow in the circuit and produce the desired response.

Since it is only necessary that the loading effect of the test circuit be negligible, the lower inductance transformer connections are used in conjunction with low impedance circuits in order to obtain a practical maximum of response. On the basis of inductance magnitudes available, circuits of up to 20 ohms impedance may be studied.

c. Multiple-Surge Amplifier

In order to keep the size and required power of the outfit within reasonable limits, it was found necessary to amplify the voltage waves appearing across the circuit to be measured. The amplifier was specially designed for this application and is shown diagrammatically in figure 4. It has an overall amplification of 180 times which falls off less than 10 per cent for frequencies down to 10 cycles per second and up as high as 500,000. Tests with the oscillograph electric transient analyzer showed that standard $1^1/_2$x 40 waves would be passed by the amplifier without measurable distortion. The output voltage is linear with respect to input up to 230 volts crest, while at 300 volts crest the output is only 8 per cent below the linear value. It might be noted that 230 volts gives full scale deflection on the cathode-ray oscillograph used. The input of the amplifier has a sufficiently high impedance so that the effect on the performance of the test circuit is negligible except in rare cases where 50,000 ohms shunt resistance will cause noticeable damping, or where 100 micro-microfarads additional capacitance will change the frequency appreciably. The amplifier contributes to the effective equipment capacitance which is about this value.

d. Cathode-Ray Oscillograph

The oscillograph used has a medium persistence screen 5-inch tube operated at 3,000 volts. All deflection plate leads are brought out directly to terminals and another terminal is provided which allows application of beam initiating impulses to the grid of the tube.

e. Camera

The camera used has an $F2$ lens with a 6.5 inch focus front lens and gives a record approximately $^1/_4$ the size of the actual image of the tube screen. Analysis of records is facilitated by projection of an enlarged image on a surface which may be provided with cross-section lines. With high-speed film good records may be obtained by exposures of $^1/_{10}$ to $^1/_5$ of a second, depending on sweep speed and beam intensity used. Of course, since the phenomenon appears on the tube screen as a standing wave, a slower camera could be used with correspondingly greater exposure.

Operation and Performance

a. Connection and Measurement

As may be seen from its picture in figure 2, the equipment is quite portable and may be set up at any point where a measurement is desired. The only requirements are a source of 110–120 volt 60-cycle power and access to the circuit to be measured, which must be deenergized.

The units are connected together and to the circuits as indicated in figure 3. If the approximate impedance of the circuit is known as is generally the case, the proper combination of coils in the multiple surge transformer can be selected immediately; although if the impedance is not known, the operator is able with a little experience to make the selection by trial. With the equipment in place, measurements may be made directly and rapidly, since with the transient recovery voltage waves standing on the tube screen the effect of any change made in the circuit is immediately apparent.

b. Performance on Lumped-Constant Circuits

As a general demonstration of the analyzer performance, recovery voltage characteristics for the three lumped constant parallel *L-C* circuits of figure 5 singly and in various combinations are shown in the oscillograms of figure 6. It may be seen that the characteristic frequency, amplitude, and damping of each circuit as seen in curves *A*, *B*, and *C* are also present as component parts of the more complex waves of *D*, *E*, *F*, and *G*. Values measured from these records are compared in table I with values calculated from the known circuit values of capacitance, inductance, and resistance.

The comparison based on frequency, amplitude, and damping shows generally good agreement. The maximum deviation in frequency is 5 per cent and this is in the case where the measured value is based on a single cycle. Since the amplitudes should be proportional to circuit inductances, the comparison is made between inductance ratios and ratios based on *y*-axis intercepts of the voltage wave envelopes. Here again the measurement based on the single cycle is subject to some inaccuracy and the greatest deviation is about 20 per cent. For damping the greatest discrepancy of about 10 per cent is not unreasonable since no account was taken of the high frequency losses of the capacitor units.

The oscillograms of figure 7 show the increased damping provided by the connection of resistance in parallel with circuit No. 2. Calculation of damping for these conditions gives the same degree of agreement as found in table I.

Calibration of the time scale for these records is obtained by connecting the analyzer to a circuit with a known natural frequency. A 40 kc timing wave is included in both figure 6 and figure 7. Since it is only necessary that the current be of the desired linearity without restriction on the absolute rate of rise, the value provided by the most appropriate transformer connection is used and a convenient voltage amplitude is obtained by adjusting the amplifier gain. The amplitude of the wave appearing on the screen is therefore arbitrary. In cases where actual values of voltage are desired, a scale may be assigned by taking the axis of the lowest frequency oscillation as equal to the crest value of the rated normal frequency circuit voltage. The determination of this axis may sometimes be facilitated by introducing damping resistance as described in the preceding paragraph.

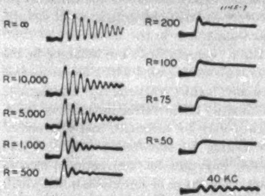

Figure 7. Recovery-voltage analyzer records showing damping effect on circuit 2 of parallel resistance of value indicated on each curve

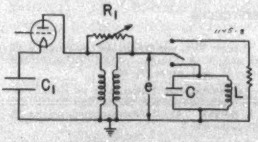

Figure 8. Connections for simulation of off-zero current interruption

C_1—Multiple-surge generator capacitance
R_1—Adjustable resistance 20,000 to ∞ ohms
e—Voltage measured with amplifier and oscillograph
C—0.0018 microfarad
L—1.35 millihenries
R—2 ohms noninductive resistor for current measurement

The range of load conditions under which satisfactory performance of the analyzer may be expected was established by measurements on circuits of the above type with natural frequencies ranging from 1 to 250 kc and with inductances up to 50 mh. While in special cases some lowering of frequency or increase in damping may be caused by the loading of the circuit by the equipment itself, particularly the amplifier as mentioned above, it may be said that the analyzer is adequate for the range of conditions which might be encountered in power circuits.

An interesting sidelight in the study of transient recovery voltage characteristics is the extension of the current injection method to simulate pre-zero interruption. This may be done by adding a d-c component to the normal injected current and is accomplished electrically by providing a resistance path directly between the multiple surge generator and the test circuit as shown in figure 8. Except that this resistance must be high compared to the load impedance, its magnitude may be varied to control the relative magnitude of the d-c component and hence the amount of pre-zero "chopping" simulated. Of course, if the "a-c" component is eliminated by disconnecting the secondary of the multiple surge transformer, interruption of d-c will be simulated.

A demonstration of the effect of pre-zero interruption on the transient recovery voltage is given by the oscillograms of figure 9 which were taken with the figure 8 circuit. The records of current were obtained by switching the analyzer output to a 2-ohm non-inductive resistor. Since the only variable was the resistance *R*, the relative amplitudes of the voltage waves represent over-voltage conditions caused by pre-zero "chopping."

c. Performance on Actual Power Circuits

A rather thorough check of field performance of the equipment was made on the test circuits of a high power switchgear testing station where some sixty different circuit arrangements were studied. Values measured from the analyzer oscillograms showed close agreement with those obtained from high-speed cathode-ray oscillograms taken during actual interruption tests, and in most cases with calculated values. Where there was disagreement between the calculated and analyzer results, the interruption test oscillograms checked with the analyzer records.

Typical transient recovery voltages are shown in the oscillograms of figure 10. Here analyzer records are superimposed on regular cathode-ray oscillograms and good agreement is shown. The small differences in the first part of the wave are due to modifications of the transient recovery by the circuit breaker used in obtaining the oscillograms. Also the method of determining the voltage calibration for the analyzer records is illustrated in this figure. As described above the axis of the lowest frequency oscillation is taken as a voltage equal to the crest

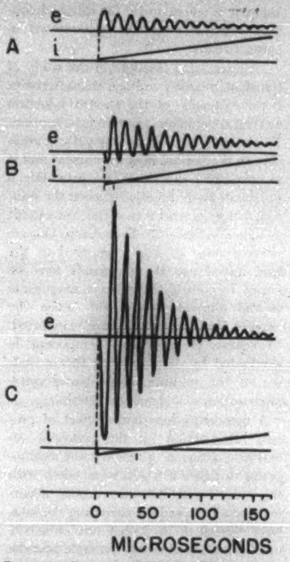

Figure 9. Recovery-voltage analyzer records obtained with figure 8 connections showing effect of off-zero current interruption

A. Voltage and current records, $R = \infty$ interruption at zero

B. Voltage and current records, $R = 200{,}000$ ohms, interruption 9 microseconds before zero

C. Voltage and current records, $R = 20{,}000$ ohms, interruption 34 microseconds before zero

value of the rated voltage of the circuit being measured. For *A* with a 4,200-volt circuit this value is 5.9 kv. For the 8,400-volt circuits of *B* and *C* it is 11.9 kv.

The analyzer has proven useful in determining the characteristics of test circuits, particularly special high recovery rate arrangements where this information was desired in advance of interruption tests. Analyzer records may also be used for comparison with conventional oscillograms to show modifications of the transient recovery voltage caused by the interrupting device itself. In addition, it is frequently desirable to know the characteristics of individual circuit elements and application has been made to transformers and reactors, illustrations of which have been published by Bewley.[15]

Conclusion

A portable device based on the multiple surge testing technique and utilizing the current injection method is now available for the determination of the transient recovery voltage characteristics of circuits and apparatus in the laboratory or field. These characteristics are obtained in the form of oscillograms which are analogous to the regular cathode-ray oscillograms ordinarily taken during interruption tests. They may be measured and interpreted according to standard practice[7] in the same way that the conventional records are. The range of conditions under which satisfactory performance may be expected includes natural frequencies from 1,000 to 250,000 cycles per second and load impedances up to 20 ohms.

A Turbine-Governor Performance Analyzer

W. O. OSBON
MEMBER AIEE

Introduction

IN the modern interconnected power system the steam turbine governor plays a very important role. Its performance has an important bearing on system stability, effect of load swings, tie line load control, frequency regulation, and other related phenomena. Consequently, within the last few years there has been an increasing interest in the subject of steam turbine governor performance. Numerous papers[1] dealing with this subject presented at recent AIEE and ASME meetings provide ample evidence of this increased interest. These papers and the discussions which they have elicited reveal a need for improved means of obtaining complete and accurate measurements of turbine governor performance characteristics.

Operating engineers and turbine governor designers alike have felt the need for better measuring instruments. The principal concern of the central station engineer is the maintenance of a high quality of service for his consumers with the minimum operating cost. Accurate measurements of governor characteristics will often reveal imperfect operation and suggest means for improving performance or for increasing operating efficiency. The designer, on the other hand, is concerned with meeting the customer's requirements as to the operating characteristics of the governor. He must also contend with such design problems as the stability of the governor as a speed regulator, and the elimination of spurious effects such as may be caused by friction, mechanical imperfections in fly-ball governors, and by fluctuations in oil supply pressure in hydraulic governors. As a result of the designer's more recent efforts, the modern turbine governor has been developed to a point where existing measuring instruments are no longer adequate for determining its performance. The art of turbine control has, in fact, progressed to a stage where further major improvements are dependent to a considerable extent upon greatly improved instrumentation.

Previous instruments used for checking turbine governor performance have in general possessed limitations which leave their accuracy open to question, or which render them inconvenient to apply and use. Ordinary graphic frequency meters, pressure recorders, and recording tachometers, although entirely satisfactory for the purposes for which they were intended, do not respond rapidly enough to measure accurately the characteristics of the modern turbine governor. In many instances instruments for measuring certain essential quantities, particularly valve travel and hydraulic pressures, have been more or less makeshift, making their application to the turbine and the taking of simultaneous observations a difficult and irksome undertaking.

It is the purpose of this paper to describe a completely coordinated set of recording instruments which have been especially designed for analyzing the performance characteristics of steam turbine governors. These instruments are characterized by their wide range of measurements, their sensitivity, and by their ability to follow changes many times more rapid than can be followed by usual recording instruments capable of measuring similar quantities.[3,4]

General Requirements

The important governor characteristics; namely, sensitivity (or dead-band), speed regulation—both static and dynamic, speed of response, overspeed performance following a load dump, etc., can all be deduced from simultaneous measurements under appropriate conditions of instantaneous values of the following quantities:

1. Electrical output of the generator.
2. The mechanical travel of the turbine steam valve.
3. Various hydraulic pressures within the governor.
4. Angular velocity of the turbine shaft.

In order to overcome the limitations of previous instruments for measuring these quantities, certain features which were deemed essential to satisfactory measurement of the important governor characteristics were incorporated in the new governor performance analyzer. Some of these features which are common to the measurements of all the above quantities are:

> First, unity of design permitting the recording of all quantities, or any combination of them, on a single chart thus allowing visual correlation of the various quantities to each other and to time.
>
> Second, ability to record both direct and alternating components with frequency-response characteristics substantially flat from zero to 50 or 60 cycles per second if feasible.
>
> Third, provision of indicating instruments so that the average value of each quantity can be determined at a glance.
>
> Fourth, complete functional design so that makeshift and "haywire" set-ups can be avoided in the field.
>
> Fifth, complete portability permitting the instruments to be set up and used with equal facility in the laboratory, in the shop, or in the field.

A sixth very desirable feature is the ability to record directly by pen or stylus on a paper chart, thus obviating the inconveniences of photographic recording. However, no multi-element recorder having a sufficiently high frequency response is now available, and due to the urgency of the governor analyzer development, it was considered inadvisable to undertake the development of such a direct-writing recorder for this application. It was decided, therefore, to use the standard oscillographic method of recording at least for the present. If a suitable direct recorder should eventually become available, the instruments to be described can be adapted to it with little difficulty.

Generator Output

For measuring electrical load delivered by the generator, it was thought desirable to provide various full scale ranges conveniently spaced between 1 and 200 megawatts with an accuracy of measurement of the order of ±2 per cent. The decision to use a standard oscillograph made the re-

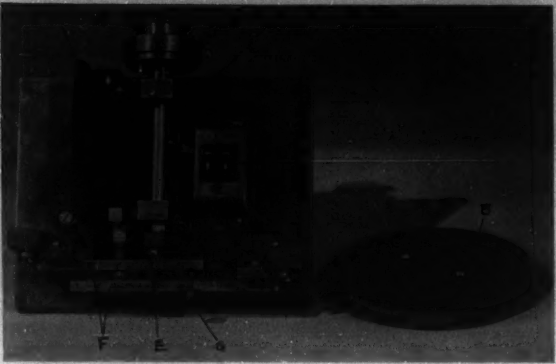

Figure 1. Valve travel recorder

A—Small pulley, *B*—large pulley, *C*—friction clutch, *D*—shaft, *E*—traveling nut, *F*—double-lever system, *G*—ratio-adjusting thumbscrew, *H*—magnetic strain gauge

cording of electrical load a simple matter, since there is already available a polyphase average watt oscillograph galvanometer which measures true watts in three phase circuits. The accuracy of this element is of the order desired, and the frequency response adequately meets the requirements, being flat to about 30 cycles per second, down approximately 10 per cent at 40 cycles per second, and down about 50 per cent at 60 cycles per second. The various full scale ranges can be obtained by using appropriate instrument transformers which are available in all central stations.

Steam-Valve Travel

The device for measuring turbine steam valve travel is illustrated in figure 1. A steel wire with one end attached to the valve operating lever is wrapped around one of the pulleys with the free end of the wire spring-loaded to insure accurate following. As the operating lever moves, the pulley and the shaft rotate proportionately. The traveling nut at the end of the shaft converts the rotary motion into linear motion, which is transmitted to a magnetic strain gauge[2] through the double lever system illustrated. The levers are mounted on crossed spring pivots to minimize friction and to eliminate lost motion.

Two pulleys are provided, one four inches in diameter and the other one inch in diameter. The smaller pulley can be exposed to use only by removing the large pulley, thus insuring the minimum moment of inertia when using either pulley. The ratio of the lever system can be adjusted to any one of four values by moving the thumb-nut to the appropriate tapped hole in the lower lever. The four lever ratios and the two pulley sizes provide a forty-to-one range of full scale motions. The instrument is proportioned so that valve motions of 0.2, 0.5, 1, 2, 4, and 8 inches give full scale deflection of the magnetic strain gauge. Motion of the strain gauge is converted into proportional variations of an electric current which are recorded by one element of the oscillograph. Thus the full travel of the largest steam turbine valve or operating piston, which may occur for example during a load dump test, may be recorded by the instrument as well as the minute motions of the order of $^1/_{16}$ inch or less which occur during normal operation of a highly sensitive governor.

A spring-loaded friction clutch is interposed between the pulleys and the shaft. This clutch, operating in conjunction with a pair of pins in the base and shaft clutch plate respectively, limits the rotation of the shaft to slightly less than one revolution. This feature serves to protect the instrument when the pulley is rotated through more than one revolution as may occur when the speed changer setting of the governor is shifted while the instrument is connected to the valve operating arm.

The frequency response of the valve travel recorder is limited to a value somewhat less than the natural frequency as determined by the inertia of the rotating parts of the recorder and by the stiffness of the wire connecting it to the valve operating lever. In order to obtain as high a natural frequency as possible with a particular wire, the force required to drive the recorder and its moment of inertia have been kept as small as practicable. The conversion of motion by the recorder into a proportional electric current permits mounting the unit very close to the valve lever so that a short and consequently stiff connecting wire may be used. With reasonable care in connecting the unit to the lever no difficulty is experienced in obtaining substantially flat frequency response to 60 cycles per second or higher.

Hydraulic Pressure

The oil pressures of interest in measuring governor performance are (1) the main pump pressure, (2) the speed-sensing impeller pressure (in the oil governor), (3) the transformed pressure, and (4) the pressures acting on the top and bottom of the valve operating piston. In order to cover the range of instantaneous values of these pressures three full-scale ranges were considered necessary, as follows: One pound per square inch variation in any average pressure up to 75 pounds per square inch; five pounds per square inch variation in up to 75 pounds per square inch average; and 50 pounds per square inch variation in up to 150 pounds per square inch average.

The device developed to measure these pressures is illustrated in figure 2. The pressure being measured is applied to the inside of a bellows, one end of which is fixed while the other end is attached to a lever. The motion of the lever is restrained by a stiff calibrating spring and

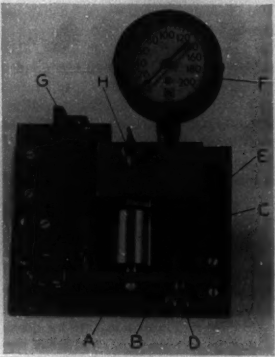

Figure 2. Oil-pressure recorder

A—Bellows, *B*—lever, *C*—calibrating spring, *D*—thumb nut for spring-force adjustments, *E*—needle valve for pressure gauge, *F*—pressure gauge, *G*—magnetic strain gauge, *H*—air drain is measured by means of a magnetic strain gauge. The spring force can be adjusted by means of the thumb-screw to balance the force due to the average pressure within the bellows.

Two different units are provided. One is used for the one-pound and five-pound full scale ranges, the shift from one scale to the other being made in the electric circuit associated with the strain gauge. The other is used for the 50-pound full scale range. The two units are identical except for the size of the bellows and the stiffness of the calibrating spring. Both are provided with gauges to indicate the average pressure. The natural frequencies of the units as determined by the spring stiffnesses and effective inertias of the moving parts are of the order of 140 cycles per second for the low pressure recorder and 170 cycles per second for the high pressure unit. With natural frequencies of this order the frequency responses of the units will be flat to well above 60 cycles per second.

Figure 4. The inductor generators

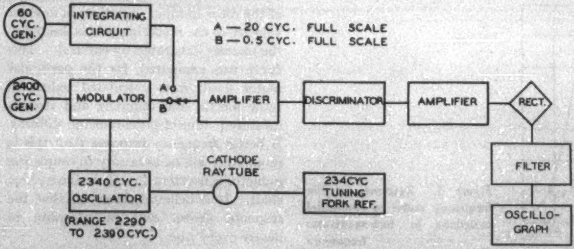
The 2,400-cycle generator is nearer the motor. A brass collar at the end of the rotor corrects for the unbalance caused by truncating the 60-cycle rotor

Angular Velocity

Although angular velocity of the turbine shaft is the quantity measured by the speed-sensing element of the governor, the ends of the shaft in many instances are not available for the attachment of a speed measuring device suitable for governor performance analysis. For this reason a small frequency-measuring synchronous motor driving two inductor generators is used. The motor is connected through a suitable transformer to the generator terminals so that its speed, within certain limitations to be discussed later, is an accurate measure of the generator frequency. Except for a small error due to variations in phase angle between the terminal and generated voltages, the generator frequency is in turn proportional to the speed of the turbine. Whenever it is necessary to avoid the error and limitations just mentioned, provision must be made for driving the inductor generators directly from the turbo-generator shaft. The synchronous motor drive has the advantage of simplicity and also permits the frequency meter described below to be used for the investigation of other problems not specifically related to governors, as for example, the relation between system frequency and tie line load variations.

Two full scale ranges are provided for the frequency meter: a wide range scale extending from 50 to 70 cycles per second to be used, for example during load dumping tests to measure overspeed characteristics; and a sensitive scale giving full scale deflection for ±0.25 cycle variation in a base frequency which may have any value between 59 and 61 cycles per second. In the instrument described below the sensitivity and accuracy are of the order of one per cent of the corresponding full scale ranges for the two scales.

Figure 3. Block diagram of frequency meter



The general scheme of operation of the frequency meter, which is by far the most complicated of the governor analyzer instruments, is illustrated by the block diagram, figure 3. One of the inductor generators produces a nominal frequency of 60 cycles per second for the wide scale range and the other generates a nominal frequency of 2,400 cycles per second for the sensitive range. As the turbo-generator frequency swings throughout the full range of the insensitive scale, the frequency of the 60-cycle generator varies between 50 and 70 cycles per second, and with constant excitation the generated voltage will vary proportionately. As it is desired to use only the frequency variations, an integrating circuit is interposed between the 60-cycle generator and the measuring circuits to eliminate the voltage variations. The output of this integrating circuit is then a true frequency-modulated wave whose amplitude is constant and whose frequency varies throughout the full scale range. This frequency-modulated signal is amplified and applied to a carefully designed discriminator circuit which, for a constant input voltage, gives an output proportional to the difference between the applied frequency and 50 cycles per second. The output of the discriminator is thus zero at 50 cycles per second, has a certain value at 60 cycles per second, and has twice this value at 70 cycles per second. The effect of the discriminator, then, is to convert the frequency-modulated signal applied to it into an amplitude-modulated signal. This signal is further amplified, rectified, filtered, and applied to an oscillograph galvanometer.

When using the sensitive scale the output of the 2,400-cycle generator is applied to a modulator circuit together with the output of a variable frequency oscillator. As the turbo-generator frequency swings throughout the full range of the sensitive scale the frequency of the 2,400-cycle generator will vary from 2,390 to 2,410 cycles per second for a base frequency of 60 cycles per second. If the oscillator is adjusted to produce a frequency of 2,340 cycles per second the modulator output then will be a frequency-modulated wave varying between 50 and 70 cycles per second or throughout the same range as the output of the low-frequency generator during full scale swings on the insensitive range. By this process the turbo-generator frequency variations are increased forty times from ±0.25 cycle per second in 60 to ±10 cycles per second in 60. The output of the modulator is amplified, converted to an amplitude-modulated wave by the discriminator, and recorded similarly to the output of the integrator circuit when using the wide range scale. The voltage of the 2,400-cycle generator also varies with the driving motor speed, but these variations are not multiplied up as are the frequency variations. For this reason the error due to them is insignificant and consequently it is unnecessary to integrate the output of the 2,400-cycle generator.

In order that the base frequency for the sensitive scale be adjustable between 59 and 61 cycles per second, it is necessary that the oscillator frequency be adjustable from 2,300 to 2,380 cycles per second to give the same modulator output wave at all base frequencies. The oscillator control dial is calibrated directly in terms of base frequency.

It is evident from the foregoing discussion that accurate measurement of the average value of frequency when using the sensitive scale depends upon the constancy of the oscillator frequency. Consequently, great care has been taken to provide a highly stable oscillator circuit. In addition, a small cathode ray tube is provided for constantly checking the oscillator frequency, by means of a Lissajous figure, against the frequency of a very stable 234-cycle tuning fork which forms part of the equipment.

As implied above the oscillograph galvanometer will respond to voltage changes as well as to changes in inductor-generator frequency. It is necessary, therefore, to minimize voltage variations in the measuring circuits due to power supply fluctuations and temperature changes. Various expediencies are used to accomplish this end. The amplifier gains are stabilized by the use of large amounts of negative feedback. The discriminator circuit as well as certain other critical circuits are formed of stable elements with low temperature coefficients. The copper-oxide rectifier circuit is designed so that variations in resistance of the rectifier discs are insignificant. Finally, the voltage applied to the field windings of the inductor generators is stabilized by a gaseous voltage regulator tube. As a result of these precautions the oscillograph current varies less than 2 per cent of that corresponding to full scale range of frequency variation for ordinary room temperature changes and for power supply voltage fluctuations of 10 per cent.

Figure 6. The frequency meter

Power-supply circuits are in the lower half and the measuring circuits are in the upper half

The inductor generators have several interesting and noteworthy features. To avoid erroneous readings it is essential that the wave shapes of the generated voltages be very nearly sinusoidal. Consequently, various arrangements have been used expressly to eliminate harmonics. As illustrated in figure 4, the two generators are combined in a single assembly. The rotor of the 60-cycle generator consists merely of a short cylindrical section truncated at one end by a plane at a slight angle to the axis. With this arrangement the length of rotor under any axial element in the pole face varies as the sine of the angle of rotation, and the voltage generated due to a uniform angular velocity is theoretically a sine wave. There is some distortion, however, mostly second harmonic, due to fringing of the flux at the edges of the rotor. This distortion is eliminated by using two diametrically opposed field structures with their windings connected so that the fundamental voltages add while the even harmonics cancel out.

In the 2,400-cycle generator even harmonics due to flux fringing are eliminated by a push-pull field arrangement similar to that used in the 60-cycle generator. The third harmonic and its multiples are eliminated by making the circumferential pole width equal to one third of the rotor tooth pitch. Finally, the fifth harmonic and its multiples are eliminated by a suitably proportioned trapezoidal rotor tooth shape suggested by Mr. C. R. Hanna. Thus the only harmonics not taken care of in the design of the generator are the 7th, 11th, 13th, 17th, etc. These are of such high order and have such small magnitude due to the smoothing effect of flux fringing that they are of no consequence.

The response of the frequency meter to sinusoidal variations in turbo-generator frequency is shown in figure 5. Curve *A* in this figure represents the frequency response of the synchronous motor which drives the inductor generators and illustrates the limitation mentioned earlier in connection with the relationship between motor speed and turbo-generator frequency. Mechanically, the motor consists of a rotating mass coupled to the revolving field produced by the voltage applied to the stator windings. The coupling is provided by the stiffness due to the synchronous torque of the motor and by the damping due to the squirrel cage winding on the rotor. Because it is not feasible to design synchronous motors with nearly perfect coupling, the response of the rotor to rapid variations in angular velocity of the revolving field is limited in the manner illustrated by curve *A*. This curve was computed, for the particular motor used, from calculated values of rotor inertia and damping and from a measured value of synchronizing stiffness. If better frequency response than this is required it will be necessary to couple the inductor generators directly to the turbine shaft. It is believed, however, that the response shown will be adequate in nearly every case.

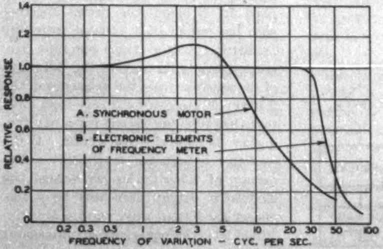


Figure 5. Response of the frequency meter to sinusoidal variations in turbogenerator frequency

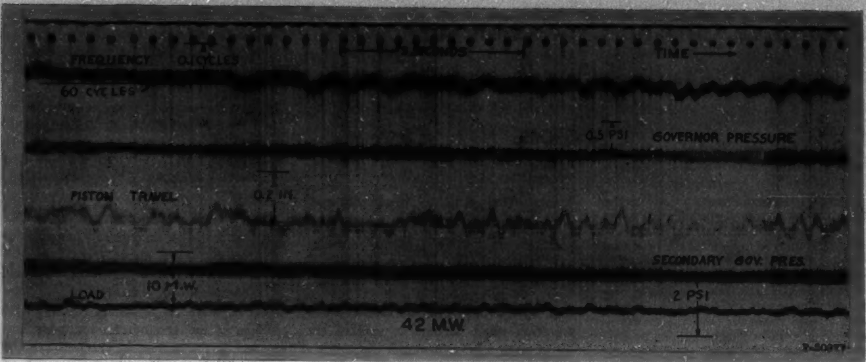

Figure 7. A typical record taken with the turbine-governor analyzer from a modern hydraulic governor controlling a 35,000-kw 3,600-rpm turbogenerator

Curve *B* in figure 5 shows the measured frequency response of the electronic parts of the frequency meter including the oscillograph. This response is very nearly the same as that of the smoothing filter connected between the rectifier and oscillograph, indicating that this filter is the limiting element. The response of the electronic elements of the frequency meter, therefore, can be improved if necessary by using a more elaborate filter.

The assembled frequency meter is shown in figure 6. The meters on the panel indicate generator field current and average turbo-generator frequency, respectively. For simplicity of operation the controls have been kept to a minimum. They include the following: base frequency adjustment, generator field current control, range selector switch, oscillator vernier, and sensitivity control. The cathode ray tube for checking the oscillator frequency is in the center below the base frequency dial. The tuning fork and the inductor generators with their driving motor form separate units.

Conclusion

It has been demonstrated in several applications of the new turbine governor performance analyzer to actual field tests that a minimum of time and effort is expended in both preparation for and during the tests. Furthermore, the information obtained is complete and easily interpreted by anyone familiar with governor characteristics. Figure 7 is a portion of atypical record. A complete test procedure for the use of the instruments was cutlined in a recent paper by A. F. Schwendner.[5]

The instruments themselves are rugged and foolproof and can withstand considerable abuse. When not in use and during transit they are contained in five rugged carrying cases which improve the portability of the equipment.

It is believed that extensive use of the new instruments will add greatly to the operating engineer's knowledge of the characteristics of his governors, and show the governor designer the way to noteworthy improvements in design.

Sensitive Ground Protection for Transmission Lines and Distribution Feeders

ERIC T. B. GROSS
MEMBER AIEE

Synopsis: If ground fault coils are used in high tension overhead systems and underground cable networks, earth leakage relays may be employed to indicate the location of single ground faults. The influence of the contact resistance at the point of the ground is explained. Earth leakage relays in compensated networks, their operation in radial and meshed networks, and the means for determining their correct operation by tests, are described. The paper is based on the practical experiences gained from such installations in England and in Continental Europe.

1. Introduction

It has always been important to locate the line in a transmission or distribution network which is affected by a ground fault. A general satisfactory solution has not been found to this problem. Therefore, it seems advisable to report on the application of wattmeter-type relays for sensitive ground fault protection in compensated networks. Such relays have been used very successfully in overhead line and underground cable systems in European countries in the past.

The expression "compensated networks" means that earth fault coils (arc suppression coils, grounding arc suppressors, ground fault neutralizers, and resonant grounding reactors) are in use. This means that at the point of the fault the charging current to ground of the system is compensated by the inductive current of the earth fault coil. If the coil is exactly tuned, the fault current at the point of the ground is very small. It consists of the in-phase component of the fundamental wave of the charging current to ground and some higher harmonics. The harmonics shall not be considered in the following, as their influence on earth leakage relays is not of any importance.

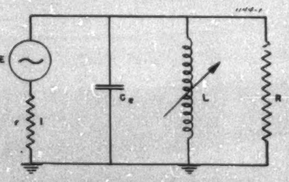

Figure 1. Simplified diagram of a compensated network, one phase of which is grounded through a resistance r

As far as ground faults in high tension systems are concerned there exist two protective schemes which are fundamentally different and which influence nearly every problem in connection with high tension power transmission and distribution. One scheme consists of the direct grounding of the power transformer star points, while the other uses earth fault coils. In the case of solidly grounded neutrals, which shall not be considered in this paper, ground faults are short circuits and the defective line has to be switched off; in the case of compensated networks no dangerous short circuit currents occur in connection with single phase-to-ground faults. It is then possible and permissible to continue operation under steady ground fault conditions.

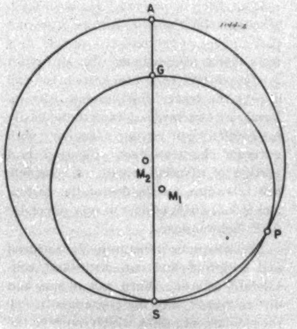

Figure 2. Circle diagrams

Circle M_1: displacement of the neutral corresponding to the simplified diagram, figure 1. Circle M_2: displacement of the neutral when no earth-fault coil is used, and when r varies

The earth leakage relays, which will be described more closely in the following, can be and have been used in radial systems both for signalizing the grounded feeder or switching it off. In interconnected systems, it is not equally easy to use these earth leakage relays for isolating the defective line, and the relays have been in use in the past mostly for signaling; however, for some systems a selective switching off system has been developed and has worked satisfactorily.

In this paper will be considered only how wattmeter-type earth leakage relays, influenced by the neutral-to-ground voltage and the residual current (mutual return of the three current transformers) operate in compensated networks. It is of special interest to investigate first how their sensitivity is influenced by the resistance to ground at the point of the fault. The theory and operation of earth fault coils has been covered in previous publications. We know from these investigations that the simplified diagram of a compensated network[1] is given by figure 1, where E is the negative phase voltage of the grounded conductor, impressed on the system at the point of the fault. The capacitance to ground of the lines is represented by C_e; L is the inductance of the earth fault coils; R is a resistance which represents the line losses and the losses in the coils; r is the contact resistance at the point of the fault.

The fault current I is greatly reduced when C_e and L are in resonance, as R is, on the average, from ten to twenty times greater than ωL. For this trap circuit I becomes $I=\frac{E}{R+r}$, and this is the in-phase component of the fault current. We can see from this immediately that the application of a "grounding transformer," for limiting the single phase short circuit current to about 20–40 amps. is[2] practically the same as a badly tuned earth fault coil, since the capacitances to ground will have an effect.

2. Influence of the Contact Resistance at the Point of the Ground

An exact analysis of the circuit leads to the conclusion that the fault current does not change very much when the tuning of the earth fault coil is not quite correct; as it is very easy to maintain nearly correct tuning, it may be considered in the following that the coil is in tune. The fault current becomes then exactly $I=\frac{E}{R+r}$. R will always be a rather high resistance in comparison with r. If

we assume, for example, that the ground fault I_e for an uncompensated 25 kv overhead line system is $I_e = \frac{E}{\omega L} = E\omega C_e = 20$ amps., then the in-phase component will be about 2 amps; hence we get $R = \frac{25{,}000}{2\sqrt{3}} = 7{,}200$ ohms, and we see that I will vary only within narrow limits, if r varies between, say 0 and 1,000 ohms. One of the advantages of the earth fault coil in this connection is, therefore, that the earth leakage relays operate under a rather constant current.

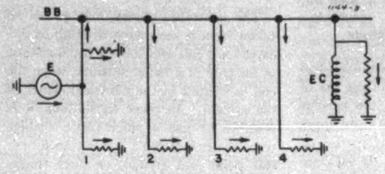

Figure 3. Radial network

Distribution of the in-phase component of the residual current. Ground fault on feeder 1

As r is the contact resistance at the point of the fault, Ir is the voltage-to-ground of the conductor with the fault; the neutral-to-ground voltage then becomes IR. Since $IR + Ir = E$, we see in figure 2 that this vector SA is divided by the ground potential (point G) in the ratio $R{:}r = SG{:}AG$. Since r is much smaller than R, we may express the action of the earth fault coil as reducing the voltage-to-ground of the faulted conductor. Without the application of an earth fault coil the fault current I_u would be

$$I_u = \frac{E}{\sqrt{r^2 + 1/\omega^2 C_e^2}}$$

and for the voltage to ground we get $I_u r$. In this case we have neglected R, as its influence is rather small; however, figure 2 will give an accurate picture.

If we again assume $I_c = 20$ amps. as charging current to ground of a 25 kv network, we find $E = 14{,}400$ volts, $1/\omega C_e = 720$ ohms, and if $r = 720$ ohms, the voltage-to-ground of the faulted conductor becomes $I_u r = E \div \sqrt{2} = 10{,}200$ volts. On the other hand, if a correctly tuned earth fault coil is used, with the same $r = 720$ ohms, and the other data given as above ($R = 7{,}200$ ohms, $I = 2$ amps., $I_c = 20$ amps.), the voltage-to-ground of the faulted conductor becomes only

$$E\frac{r}{R+r} = 1{,}310 \text{ volts}$$

which is considerably smaller.

As already mentioned, the neutral-to-ground voltage is used for the polarizing of the earth leakage relays. Its value is the phase voltage of the system for a direct ground, and nearly as much for an earth fault through a contact resistance. As the voltage-to-ground of the grounded conductor is 1,310 volts in our example, the neutral-to-ground voltage becomes $SG = SA - AG$ or $SG = 14{,}400 - 1{,}310 = 13{,}090$ volts. In general we get $IR = \frac{ER}{R+r} \approx E(1 - r/R)$, as r/R is usually small compared with 1. This means that the earth leakage relays in a compensated network will operate also under a rather constant voltage.

Figure 2 shows the results of a precise analysis of the circuit.[3] The smaller circle, center M_1, is the diagram for the neutral-to-ground and the line-to-ground voltages when an earth fault coil is used and its tuning is changed steadily by varying L while C_e, r, and R are kept constant. The tuning is exact at G, and therefore $AG{:}SG = r{:}R$. The intersection of the two circles, point P, gives the voltages when the earth fault coil is switched off. The bigger circle, center M_2, is the diagram for the same voltages when no earth fault coil is applied; here, r is variable, and R and C_e are constant. The smaller circle is divided by S and G into two parts; at all points of the circle on the right side of SG there is undercompensation of the charging current to ground, i.e., the inductive coil current is smaller than the capacitive ground current. At all points on the left side of SG there is overcompensation. The coil is at resonance at G, at which point the fault current has no reactive component. Point P lies on the right part of the circle, since the coil is switched off at this point.

3. Earth-Leakage Relays

In a network with an insulated neutral and no earth fault coil in use, the point of the ground fault may be considered as that part of all the sections and lines of the whole system where the charging current to ground has its greatest value. We know that the neutral-to-ground voltage should be impressed on the network at this point to give the correct distribution of the charging-to-ground current over the system. This picture of the current distribution changes, as far as the reactive component of the charging current is concerned, when earth fault coils are introduced, since they are additional reactive connections to ground. However, the coils do not influence the dissipation of the in-phase component, since the in-phase component is due to losses, which are not compensated by the coils. This implies that, for getting selectivity, only relays can be used which act upon the in-phase component of the residual current i in each feeder. This means that the relays must react to the formula $ei \times \cos\phi$, where e is the neutral-to-ground voltage and $i\cos\phi$ the in-phase component of the residual current in the feeder. The operation of earth leakage relays in a compensated network will be shown in more detail in the following.

As first example, a radial network is drawn in figure 3, where each line represents a three phase feeder (lines 1, 2, 3, 4); BB are the busbars and EC is the earth fault coil. The resistances represent the losses which are, of course, uniformly distributed over the network. If a ground fault occurs on feeder 1, the distribution of the in-phase components $i\cos\phi$ of the fault current will be as indicated by the arrows. We see that its direction is the same in all the unaffected feeders, away from the busbars and opposite to that in the faulted feeder 1. Hence a sensitive wattmeter-type earth leakage relay will detect the faulted feeder.

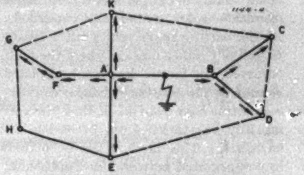

Figure 4. Interconnected network

Distribution of the in-phase component of the residual current. Ground fault on feeder *AB*

Similarly in a mesh or interconnected network, the in-phase component of the residual current is a maximum in the faulted line, and it is very easy to find this section of the transmission or distribution system from the operation of the signalizing earth leakage relays. Figure 4 shows a part of such an interconnected network, the dotted lines indicating that it is really a mesh network. If, for example, the fault occurs at the line AB, the distribution of the active component of the

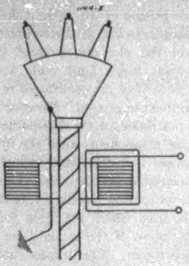

Figure 5. Ring-type current transformer

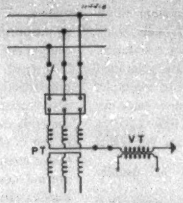

Figure 6. Testing connection when a single-phase voltage transformer is used for supplying the neutral-to-ground voltage

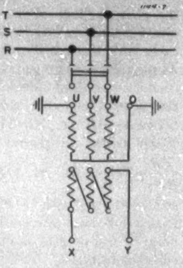

Figure 7. Testing connection when a three-phase voltage transformer is used for supplying the neutral-to-ground voltage

fault current will be as indicated by the arrows. The figure shows clearly that the earth leakage relays will operate on both ends of the faulted line, while on all other lines we find relays operating only on one end. On *BC*, for example, only the relay at *C* will operate thus indicating the direction in which the ground fault is located.

Relays acting on the in-phase component of the residual current could also be used in uncompensated (fully isolated) networks as the distribution of the in-phase component of the residual current is independent of the presence of earth fault coils. However, earth leakage relays have been used mostly in compensated networks since the great reduction of the fault current permitted continuous operation under ground fault conditions. As the earth leakage relays are a means to find out rather quickly where the fault occurred, the faulted line can be isolated as soon as the necessary changes in interconnection have been made, thus preventing any substation from becoming de-energized. This method has been used in compensated networks in Continental Europe for many years and improved by past experience.[4] The method has proved to work very satisfactorily also in Great Britain, where earth fault coils and earth leakage relays have been used only for the last few years,[5] but are now being used in an ever increasing extent.

The earth leakage relays are wattmeter-type relays, polarized by the neutral-to-ground voltage and the residual current. The voltage coils in use are of the normal relay type, but the current coils are usually made from more turns of a smaller wire, in this way increasing the sensitivity of the relay. If accurate current transformers were at hand, they could be used successfully, even with an in-phase component of only 1 amp. or less, and with a current transformer ratio of 100/5 or 200/5 amps. For smaller primary residual currents special current transformers may be advantageous.[6] In Great Britain metal clad switchgear is used almost exclusively; therefore the overhead line sections are usually terminated through a short cable run, and ring-type transformers, figure 5, have been found as a cheap and good solution.

As the ground fault is no longer a single phase short circuit, no overcurrents now appear in connection with that kind of fault in a compensated network; hence it should not be necessary to protect the current winding of the earth leakage relays against damage by heavy excess currents. However, short circuit currents are possible through the earth leakage relay coil in the case of a double ground fault (i.e. two grounds on different line sections in different phases). In networks supplied by stations of very high generating capacity, additional excessive current protective relays in the asymmetry circuit have been used. These overcurrent relays shunt the sensitive earth relay coil and thus protect it against damage by the heavy short circuit currents in case of a double ground fault. Such overcurrent relays are useful too in another respect; they hinder the operation of earth leakage relays under double ground fault conditions. A detailed investigation shows that earth leakage relays might operate incorrectly in interconnected networks under double ground fault conditions.

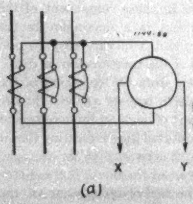
4. Connections and Testing of Earth-Leakage Relays

The neutral-to-ground voltage can be taken from a secondary winding on the earth fault coil, which is the usual method in the case of a radial network, when the coil is located in the electrical center of the system. In other substations, it is possible to use a single-phase voltage transformer between a power-transformer star point and ground, or three single-phase voltage transformers with grounded neutral and the secondary winding in delta for supplying the neutral-to-ground voltage. As has been said, we consider only fundamental questions in this paper, hence we omit some results of theoretical investigations and practical experience by which correct operation of very highly sensitive earth leakage relays was attained.[4]

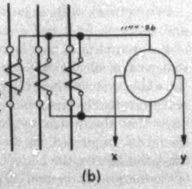
When earth leakage relays have been installed, it is advisable to check their correct operation by tests. There are two different ways of relay testing according to the various methods of getting the neutral-to-ground voltage.

(*a*). If the neutral-to-ground voltage is taken from the secondary winding of the earth fault coil, it is necessary to make actual ground faults, either on the busbars or on one or more feeders. The use of a protective resistance as artificial contact resistance is advisable; its value in ohms should be[3] about $1/\omega C_e$. Then the earth leakage relays should be tested in correct wiring connections and also with reversed voltage. If the ground is made on the busbars, of course, the relays should operate only with reversed voltage, i.e., with the wiring connections reversed.

(*b*). If the potential transformers are used for supplying the voltage coils of the earth leakage relays, actual ground faults for testing the correct operation of the relays are not necessary. According to figure 6, one phase of the power transformer should be disconnected (if the power transformer can be de-energized), provided that only a single-phase potential transformer is used which is connected between the neutral of a power transformer and ground. The potential transformer is then under a voltage-to-ground which is of the same phase angle



(*a*)



(*b*)

Figure 8. Testing connections of the three-current transformers of a line section

(*a*) Incoming power

(*b*) Outgoing power

as if there were a ground in the disconnected phase; the amount of voltage being only half of its value under actual ground fault conditions. If, however, a bank of three potential transformers is used and a similar connection is made (figure 7), the secondary winding will give a voltage of correct phase-angle, but its amount will be only about $^1/_3$ of its maximum value under ground fault conditions; the phase angle will again be that of the opened phase of the potential transformer.

To get a corresponding current in the coil of the earth leakage relay, we now make an auxiliary connection on the secondary side of the current transformers on each outgoing feeder (as shown in figures 8*a* and 8*b*). We use figure 8*b* if power is outgoing and figure 8*a* if power is incoming.

With these auxiliary connections, in both voltage and current circuits, the earth leakage relays are supplied with voltage and current under exactly the same phase-angle as would exist between residual feeder current and ground-to-neutral voltage under ground fault conditions. The earth leakage relays should then operate. If they do not, we must change the connections by reversing either the voltage or the current wires. In similarity with a wattmeter or a watt-hour meter, we are able to find the correct connections only according to the polarized and marked terminals of the potential and current transformers; however, it is always advisable to make sure by actual tests that the relays are put into service with correct connections.

5. Conclusions

(*A*). The application of resonant neutral grounding makes possible the operation of radial and network systems with permanent ground faults. This has been proved by many installations abroad, both for overhead line and underground cable systems, and with line voltages from 3,000 volts up.

(*B*). The installation of wattmeter-type earth leakage relays would give an indication of the defective section of the line. The relays act upon the in-phase component of the residual current and the neutral-to-ground voltage of the system.

(*C*). The in-phase component of the residual current is in most cases large enough to secure correct operation of the relays.

(*D*). The operation of the relays can easily be checked by simple tests.

The Communication Facilities of the U. S. Forest Service

A. G. SIMSON
NONMEMBER AIEE

FOREST protection in the United States is a job of considerable magnitude. There are, roughly, 550,000,000 acres, which are equal to the area east of the Mississippi River, exclusive of Wisconsin and Illinois, under intensive protection against forest fires. Moreover, there are an additional 138,000,000 acres needing organized forest protection.

Of this vast area, state and private agencies are responsible for about 279,000,000 acres, the U. S. Forest Service for about 208,000,000, and other Federal Government agencies for about 60,000,000 acres.

According to U. S. Forest Service records the annual number of forest fires is increasing materially, though the average size of the fires is becoming progressively smaller each decade. The fact that the average fire is getting smaller, even though there are more of them, is one encouraging evidence of the gradually increasing effectiveness of fire suppression tools and fire control technique.

Dry-battery-operated ultrahigh-frequency automatic-relay station

Upper deck—transmitter; lower deck—receiver

Comparatively recent improvements in communication facilities have undoubtedly played an important part in reducing fire losses. It is generally true that the quicker one can attack a fire the fewer men are needed to put it out, which, of course, points the way toward faster communication and transportation.

One of many examples of the importance which fire fighters place on radio communication is contained in the following quotation from a news story on the recent forest fires in Maryland:*

> "Two-way radio communication proved helpful on a large fire in northern Anne Arundel County which burned more than 3,000 acres. The department of forestry called three forestry radio cars into the area and directed them by radio from the Long Hill lookout tower in shifting fire-fighting crews from point to point.
>
> "Had radio equipment been available on the fire trucks and other vehicles, forestry officials believe the fire could have been held to half its size and much of the forest saved."

Though it is probably true that few, if any, forest protection agencies have sufficient communication facilities, the extent of these systems is surprisingly great. For example, the U. S. Forest Service is

Forest Service type M semiportable radiophone

maintaining over 60,000 miles of telephone line and operates about 3,500 radio stations. State and private forest protection agencies are reported to have about 52,000 miles of telephone line and 1,500 radio stations.

Fundamentally, all forest protection agencies have pretty much the same job to do and go about it in a similar manner, though there are, of course, differences in organization and degrees of protection.

Since I am most familiar with the operations of the U. S. Forest Service, this discussion will deal mainly with that agency.

For administrative purposes, the Forest Service divides the continental United States, Alaska, and Puerto Rico into ten regions. Within each region there is a number of national forest units—a total of more than 150.

National Forest Communication Systems

Since the national forest is the administrative unit, the communication systems are set up on a national forest unit basis.

The backbone of the national forest communication is, of course, wire line—either Forest Service lines or commercial circuits if they are available.

Radio is used where no other satisfactory means of communication are available. Nearly all of the radio communication is of an emergency nature. Ordinarily, it is not considered desirable that both routine administrative and fire traffic flow over the same radio circuits, since in time of emergency the administrative traffic would have to give way to emergency needs which would disrupt the normal forest administration.

The communication system on a forest unit falls roughly into three general classes of use, namely: (1) administrative circuits, as between the forest supervisor and district ranger offices, and between district ranger and CCC camps, ranger stations, and logging camps; (2) fire detection circuits, as between fire lookouts and lookout to central fire dispatcher; (3) fire suppression circuits, as dispatcher to patrolmen, fire crews and fire trucks, communication between main base camp and sector camps on large fires, contact with foot and aerial scouts, freighting planes, communication along the fire line, base camp contact with regional equipment depots, and communication with the mobile fireweather forecast units.

Communication on Large Fires

Modern fire fighting, especially on large fires in heavily forested regions, assumes much of the aspect of a military operation with all its complexities of staff organization, service of supply, and front line attack.

Consider, for example, a fire of the "conflagration" class—say 50,000 or 75,000 acres. The perimeter of the fire will likely be 100 or 150 miles. Several thousand fire fighters will be employed. They will be split up in camps of about 200 men each appropriately spaced along the fire line. The fire line will be in the charge of a fire chief. Directly under him will be an assistant chief, chief of service of supply (SOS), transportation chief, equipment chief, head scout, communication chief, paymaster, and sector bosses. Each sector boss is directly responsible to the fire chief for his sector of the fire.

(Lower left) Typical radio installation in Forest Service lookout

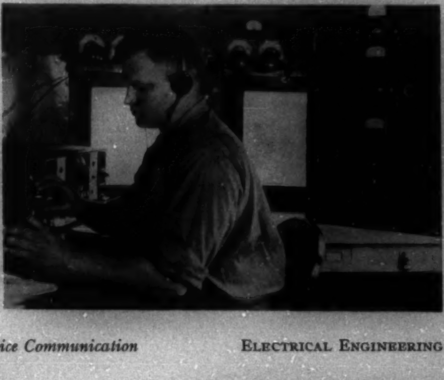
Interior of Forest Service radio trailer used on large fires



Radio communication on the fire line during "mopping up" phase of fire

Note two hose lines in use

(Right) Forest Service smokechaser "reporting in"

Fire pack includes tools, radio, emergency rations, and blanket

The main communication center will be at staff headquarters in the main base camp. From this point communication circuits will be established with the regional equipment depot, forest supervisor's headquarters, reconnaissance and transport planes, fireweather units, and the sector camps located along the fire line. The sector camps will set up local networks to communicate with the fire line, ground scouts, nearby lookouts, and various fire fighting units within the sector.

Before the advent of radio, communication along the fire line was largely by messenger, which at best is a slow and uncertain method. Consequently, there was too often a conspicuous lack of coordination among the various fire fighting units attacking a single fire. For example, one sector of the fire might be considerably overmanned or overequipped while other crews were losing ground through lack of reinforcements or apparatus. With the development of portable and mobile two-way radio, marked improvements in fire fighting tactics became possible. The entire forces can now be controlled from a single headquarters and men and machines shifted along the line as the vagaries of fire behavior dictate.

Radio Frequencies Used

Originally, forest protection radio communication was entirely in the 2–4 megacycle band. This part of the spectrum was selected because single channel transmitters were used and these frequencies exhibit the least variation in diurnal and seasonal sky wave propagation. The lower limit of the frequency band selected was also influenced by antenna length. In order to preserve portability and obtain reasonable efficiency, horizontal half-wave antennas are used. Experience has shown that the difficulty of finding a clear space in dense forests of sufficient size to stretch an antenna increases rapidly with

(Right) Automatic relay antenna, Mt. Hood, Oregon

(Lower right) Portable radio installation in "sector" fire camp

Communication unit used on large fires

length of the radiator and that 140 feet is a good compromise.

For the last seven or eight years the percentage of ultrahigh frequency stations—30 to 40 megacycle band—has increased rapidly. Frequencies in this portion of the spectrum were selected as representing the best compromise between the desirable characteristics of the ultrahigh frequencies such as minimum static, short antennas, circuit efficiencies, and the better coverage below line of sight obtainable with lower frequencies. Rapid growth in the use of the ultrahigh frequencies has been due both to improvements in apparatus and to increasing experience in the technique. Oddly enough, ultrahigh frequency systems have developed much more rapidly in the mountainous forest of the West than in the flat or rolling terrain of the East. One factor has been the discovery that, in general, the "blind" areas behind sharp mountain ridges are not nearly as sharply defined as they are in areas where the slopes are less precipitous.

Radio Equipment Requirements

Since fire behavior, suppression technique, and transportation facilities vary widely as between forest types, the types of radio apparatus employed also vary. Nevertheless, there are certain general requirements which all types must fulfill.

The equipment must have good reliability and must be consistently capable of withstanding hauling by truck over long distances on rough roads. It must withstand the vicissitudes of packhorse transportation and be workable after parachute delivery. The controls must be foolproof and the manipulation simple enough that untrained laborers may set up and operate the apparatus without difficulty. The component parts must be of standard design and commercially available to facilitate battery replacement and repairs without excessive delay, and because urgent equipment needs greatly exceed available funds costs must be kept to a minimum. In addition, the portable types must be truly portable. In regions where the standard smoke chaser's pack weighs about 35 pounds, 10 or 11 pounds are about the practical limit of additional weight he can carry for communication.

Since the portable radiophones must be low powered, it has been found desirable to restrict the power on even the semiportable units. An insufficient number of frequencies has made it necessary to repeat the same frequency well within interference range so that power must be held to a minimum if the signals from the lowest powered portables are to be protected against interference from the higher powered mobile and semiportable units.

High-Frequency Radiophones

The type *M* is the highest powered fire communication unit used by the Forest Service. It has a nominal output of 25 watts, although the full output is seldom used. The type *M* operates from an a-c power supply or portable generator. The complete unit weighs about 90 pounds, The tube line-up is: 6F6G oscillator, two 6L6G in parallel in radio-frequency amplifier, 6F6G speech amplifier, push-pull 6L6G modulators, and a pair of 83 rectifiers. A low-drift crystal maintains frequency stability. The output stage terminates in a pi matching network to accommodate a wide range of antenna or transmission line impedances.

The receiver section is a conventional superheterodyne having a minimum of operating controls.

The type *M* was designed for use at forest headquarters, central fire dispatchers, central equipment depots, and at communication centers on large fires. Since these radiophones may be expected to create interference over a radius of several hundred miles, lower powered units are substituted wherever possible.

A smaller unit of similar form designed to operate from an ordinary six volt automobile storage battery is also available. This unit has an output of $9^{1}/_{2}$ watts and is a substitute for the type *M* where commercial power is not available and where, because of "standby" requirements or for other reasons, it is not desirable to use a gas engine driven portable generator.

The most widely used three megacycle unit is the type *SPF*. For portable operation the complete unit weighs 21 pounds and has a rated working range of 20 miles. The transmitter section is crystal controlled and, as is the case in all Forest Service portable radiophones, receiving tubes are used throughout in both the transmitter and receiver sections. The nominal power output is 2.25 watts. The receiver section is a five tube superheterodyne having a sensitivity of about three microvolts absolute. Provision is made for continuous wave reception by either headphones or built-in loudspeaker.

Forest Service type SX radiophone with loudspeaker unit as used at emergency lookouts and for semiportable operation

For semiportable service a kitbox is supplied which contains heavy duty batteries and an additional half-wave antenna. This latter form was especially designed for secondary lookouts and road construction crews. The lookout installs the half-wave antenna at his station and operates his radiophone from the heavy duty kitbox batteries. When he goes to a fire he needs only to unplug the battery cable and drop the radiophone in its carrying bag to have a 21 pound portable radiophone complete with light batteries and antenna. Thus, he wastes no time in taking down the antenna and is assured

Portable radiophone used by Forest Service parachutist fire fighters

Forest Service portable type SX ultrahigh-frequency radiophone

of unused batteries for his emergency communication.

Similarly, some road crews use the half-wave antenna and heavy batteries while in camp and each morning take the portable outfit out on the job and set it up for contact with the fire dispatcher.

Though not designed for mobile operation, these units have been operated in planes, boats, and trucks where mobile equipment was not available.

Many of the fire trucks and patrol cars are equipped with two-way three megacycle radiophones. The consistent range of these installations is only about 20 miles, mainly because of antenna limitations.

Where fire trucks are employed intensively, two-way communication adds greatly to their usefulness, since it means the trucks are always "in service," even when making a run. It has enabled the dispatcher to recall trucks from false alarm runs and makes it possible to redispatch them without the necessity of returning to headquarters for orders.

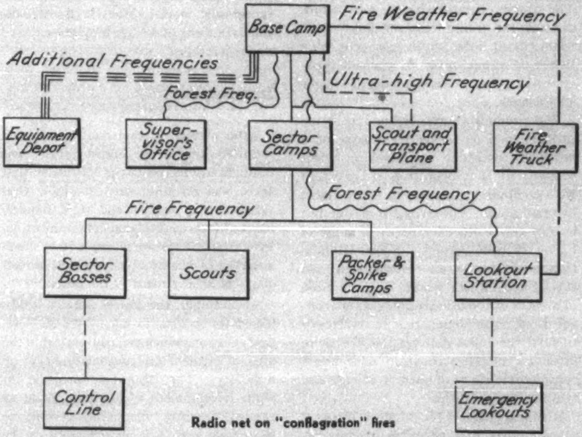
The mobile transmitters are powered by dual vibrators rather than a motor generator in order to eliminate the more difficult servicing of rotating machines and to reduce the drain on the vehicle's battery. The input at the final radio-frequency stage is about 16 watts, but only a fraction is radiated because of antenna inefficiencies. Only a very short antenna can be installed because many of the trucks operate directly on the fire line and are driven through the forests where there are no roads, with a consequent high mortality in antennas, fenders, and running boards.

The shortcomings of the antenna are offset in part by a base loading and tuning unit, but withal the reliable range of this radiophone is only 20 miles, and when possible the ultrahigh frequencies are used, instead, for mobile communication.

Ultrahigh-Frequency Radiophones

In addition to the apparatus already described an increasing proportion of forest protection radio systems utilize the ultrahigh frequency 30–40 megacycle band. Where ultrahigh frequencies are usable they offer obvious advantages over the lower frequencies. Antennas are smaller, and there is substantially no fading or static. The last named feature is especially important since 44 per cent of all fires on the national forests are caused by lightning, and frequently these lightning storms destroy wire or telephones to the point of causing serious delays in the reporting of lightning fires, with consequent heavy fire losses.

Ultrahigh frequency radiophones are used for the same general purposes as the 3,000 kilocycle equipment and are especially effective for interlookout and mobile communication and where the utmost in light-weight compactness is required.



Radio net on "conflagration" fires

The unit designed especially for lookout installation (U. S. Forest Service type *T*) has a crystal controlled transmitter of two watts power.

The receiver contains a 1A7G converter, three stages of 4,050 kilocycle intermediate-frequency amplification using 1N5G tubes, a 1H5G detector and audio amplifier, and a call-buzzer circuit utilizing a 1N5G tube. The intermediate-frequency band width is approximately 50 kilocycles. This comparatively wide band permits reception of modulated oscillators. The buzzer-alarm circuit is useful for night calls and permits installation of extension bells in the towerman's residence.

The low-drain tubes employed in this radiophone give reasonable dry battery economy, even on continuous service.

A new all-purpose portable radiophone known as the type *SX* was developed last year. This complete unit weighs about ten pounds and is applicable to uses of scouts, smokechasers, and others requiring extreme portability. Provision for selecting any of three crystal-controlled transmitter frequencies adapts the unit for operation in fixed frequency networks or ready switching from one network to another. Another useful feature is a panel pushbutton which provides a marker signal and permits setting the receiver on any of the three transmitter frequencies.

For emergency lookout use a kitbox is supplied with the type *SX*, which contains heavy duty batteries and an additional unit containing an audio amplifier and loudspeaker.

Forest Service parachute jumping fire fighters use a condensed version of this radiophone. The parachute jumper's model, which weighs a little less than six pounds, is designed to be carried in a pocket on the leg of the jumper's suit.

General use of ultrahigh frequency in mountainous regions has required the development of an automatic relay station. The transmitter section is conventional design and where—as is usually the case—dry battery is the only source of power, has an output of two watts.

The receiver presents some interesting features. Twelve tubes are used distributed as follows:

Two signal radio-frequency stages
First detector
Crystal oscillator
Frequency multiplier
Three intermediate-frequency stages
Second detector (AVC)
Fifteen kilocycle noise amplifier and rectifier
Relay control tube
Audio amplifier

The system of relay control is based upon the inherent circuit noise and variations of this noise with signal input through operation of the AVC system by the signal. A filter which passes a narrow band centered at 15 kilocycles is branched off the audio input circuit and the resultant 15 kilocycle noise component is amplified and rectified to produce control bias for the relay tube. Fifteen kilocycles is chosen because it is well beyond the range of audio intelligence and, consequently, prevents the communication signal from energizing the relay tube The system operates with the relay, which controls the transmitter, *off* under maximum circuit noise, static crashes or other heavy noise, and relay *on* when an application of a signal causes a reduction in the 15 kilocycle noise component.

The circuit is so arranged and constants proportioned as to keep the noise at a relatively constant top level (in effect limited) so that operation is consistent with combined circuit noise and variable external noise. The circuit is reliable but is only relatively tolerant as to range of battery supply voltage. Some stabilization is effected because of the high gain throughout, which results in production of a small automatic volume control voltage from noise alone; this in turn tends to hold the noise delivered to the noise filter at a relatively constant value over a considerable range of battery voltage and temperature condition.

An inexpensive filter which is incorporated in the unit permits simultaneous transmission and reception on the same antenna.

Satisfactory antennas for high altitude relay stations where icing is especially bad, as well as for lookout house and tower installations, must be extremely rugged mechanically, must provide a heavy d-c path to ground for lightning protection, and must be easy to duplicate without special materials and insulators. An antenna with the best of electrical characteristics would be almost useless unless rugged and sufficiently simple in structure to permit duplication by mechanics in the average forest central garage or machine shop. The antenna structure consists of approximately quarter-wave radiator with an integral coaxial matching section and radial arms of quarter-wave length At one-tenth wave length the coaxial matching section has a resistance of about 65 ohms at the feed point. Line voltage is substantially constant and without standing waves on the transmission line. In field tests this antenna showed a voltage ratio of about 1.8 to that attained on the *J* type antenna.

An additional point of interest in the antenna is the absence of large exposed insulators. The only insulator involved in the antenna proper is the coaxial centering ring, which is placed well inside the coaxial tubing and is thereby not exposed to the weather.

Development

After trying commercially designed radio equipment the Forest Service was reluctantly forced to the conclusion that there was no equipment available that satisfied the peculiar and rigid requirement of forest protection communication. Primarily, the problem was not so much a matter of electrical circuits as of mechanical arrangement of the units.

Accordingly, the Forest Service established its own radio laboratory in Portland, Oregon, which is fairly central to the area of greatest fire and communication difficulty. The laboratory projects include development of new equipment as needed, revision of existing models to keep pace with the current state of the art, and developments in the application and technique of radio communication.

Procurement

The procurement and inspection of all radio equipment used by the entire U. S. Forest Service is centralized at Portland, Oregon. Centralized procurement permits consolidation of orders, helps insure purchase of uniform types of apparatus, and is the most practicable method we have found of filling emergency requisitions for apparatus to be used on going fires with a minimum of delay.

Manufacturing contracts are based on competitive bids Technical specifications are not used; instead, the contractor is required to build exact duplicates of a working model which is supplied him. The whole procurement program is designed to meet unpredictable emergency demands for radio units with a minimum of delay and without carrying large reserve stocks.

Maintenance

Usually Forest Service communication equipment, both telephone and radio, is serviced and maintained by regular personnel. Much of the work is done incidentally to other duties by employees having little or no electrical training other than on forestry radio. This situation requires special consideration in the design of the radio units and in the preparation of servicing instructions.

The variety of uses to which radio can be put in forest protection is increasing as we gain knowledge of its possibilities At present we see a need for a simple, portable direction finder that can be operated by a lookout man in conjunction with his fire finder to guide smokechasers to "sleeper" fires in dense forests. These fires are often most difficult to find and have been known to smolder for weeks and to become a running fire during the next dry windy period.

A portable dry battery operated radio facsimile transmitter and receiver is needed for use by reconnaissance planes and for speeding up message traffic on large fires. Already the traffic load has reached a point where additional circuits must be established or unacceptable delay occurs.

The Modern A-C Network Calculator

W. W. PARKER
MEMBER AIEE

PRODUCTION requires power. The urgent necessity of meeting the immediate demands for electric power—due to national defense and natural growth—has created a challenge to the planning engineers. Local loads are increased and additional loads established, resulting in shifting of load centers. Such changes require increased generating and transmitting facilities. To provide for this expansion in power supply requires accurate planning to avoid waste of time, materials, or effort. The first step is the quick solution of all the electrical problems.

The A-C. network calculator provides accurate means for solving these problems. Therefore, it is appropriate to present the newly perfected features of the latest A.C. network calculators. These provide the means and methods for faster and more accurate analysis of existing or planned power systems and the solutions of electrical design and operating problems. The essential elements of a power system are reproduced in miniature replica, as illustrated pictorially in figure 1 for a simple radial feed from generator to load. The calculator reproduces systems with many generators or generating stations, transformers, lines, and loads. Readings of the miniature network on the calculator are readily converted into actual system quantities.

The electrical performance of the system can be obtained from the calculator studies. The principal studies involve:

1. Voltage regulation and load control studies for normal and emergency operation.
2. Short circuit studies for circuit breaker or protective relay application.
3. Steady state or transient stability studies for determining power limit of transmission systems.

For any of the above investigations, the various steps in the solution are:

1. Assemble and organize the data of the power system.
2. Convert these data to a base or scale suitable for use with the calculator voltages, currents, and impedances.
3. Set up the calculator network and adjust the loads and the generator outputs in accordance with the requirements of the specific problem.
4. Meter the network, obtaining the significant calculator readings such as voltage, current, phase angle, watts, and vars.
5. Reconvert these into system values.

For voltage regulation, load control, short circuit studies, and steady state stability studies, the calculator gives the desired quantities directly, requiring only conversion into system values. Transient stability studies require the same "step-by-step" method used in straight mathematical solutions. The calculator gives the electrical conditions for each step, thus not only saving tedious computations but also permitting the solution of multimachine problems with more generators than can be solved by other methods.

The demand for calculator solutions has been so great that existing facilities have been taxed to full capacity and several new calculators are being constructed. A list of calculators is given in table I.

This paper describes the most recent A-C. network calculator which, although embracing fundamental designs proven over a period of eleven years, has incorporated improved features to facilitate the setting up and metering of the calculator miniature network. A typical calculator of modern design is shown in figure 2.

Fundamental Features of Design

The engineer who uses the calculator is interested primarily in quick, dependable, accurate results. In meeting these requirements, the designer of the calculator considers accuracy, convenience, speed, space, and cost. In these considerations the choice of frequency and power level are predominant factors.

FREQUENCY

The choice of frequency is independent of the frequency of the system to be studied since impedances are used in terms of ohms. The cost and size of reactors and capacitors to cover the range of values needed indicated that a choice of frequency higher than normal would be desirable. The A-C calculator frequency has been established at 440 cycles.[2]

POWER LEVEL

The calculator has rated values for normal operation of 100 volts and 1 ampere, with maximum capacities of 400% for voltage and 300% for current. This power level was arrived at from considera-

Figure 1. **The a-c network calculator electrically reproduces actual power-system conditions**

The a-c network calculator consists of a number of adjustable resistors, reactors, and capacitors, representing the corresponding constants of the actual system, wired to suitable cords so that an actual electrical network can be reproduced in miniature. Sources of voltage whose magnitude and phase position can be varied represent generators and other synchronous machines. Distribution of voltage and current throughout the system is determined by measuring the quantities in the calculator circuits and applying a multiplying factor fixed by the scale to which the network has been set up. The conditions in an existing or proposed system can thus be observed quickly, easily, and accurately

Figure 2. A typical a-c network calculator

The cabinet on the left contains six generator units with their associated instruments for measuring voltages, currents, and power. Below the instruments are the handles for independent adjustment of voltage and phase angle. The bottom drawers contain adjustable capacitor circuits. The next cabinet contains six impedance circuit drawer sections and the master instrument and control desk. (In the calculator described in this paper a separate control desk is used.) The third cabinet from the left is a connection cabinet in which all the circuit terminals are brought out for interconnection. The other cabinets contain load circuits with associated load adjusters, auto transformers, and other line circuits

tion of instrument characteristics and the desirability of avoiding errors due to capacitive or inductive coupling. If a lower voltage base were used, the current base would have to be lowered in proportion to avoid significant inductive coupling. This, in turn, would make the power level so low that, using standard torque instruments, errors would be introduced due to their burden, or high electronic amplification would be required. If the current level were reduced to any considerable extent without reducing the voltage, it would be difficult to avoid errors due to capacitive coupling.

Details of the New Calculator

In addition to these fundamental design features, the later calculators have improved methods of setting up the boundary conditions (i.e. desired loads and generator outputs) and inserting instruments into any element of the calculator network. As a result, accurate determinations of the system conditions are obtained with a minimum of time and effort devoted to manipulation of the calculator. Generally, the solutions are on a phase-to-neutral basis with the use of symmetrical components to solve unbalanced conditions. Complete three phase representation is possible but seldom used.

Generator Units

In order to represent generators or power stations, it is necessary to apply to the calculator impedance network, voltages which are adjustable in magnitude and phase angle. The voltage adjustment corresponds to changes in excitation, and the phase angle adjustment to changes in the governor position. In setting up a specific operating condition, the voltage regulator and phase shifter of the generator units are adjusted until their voltages and currents give the desired inputs. This adjustment requires a minimum of manipulation when there is negligible regulation in the calculator units and the controls of the voltage and phase angle are independent of each other.

Each generator unit has less than 2% regulation from 0 to rated load and has independent adjustment of phase angle and magnitude. This is achieved by means of a novel combination of induction voltage regulators and phase shifter, shown schematically in figure 3. The voltage regulator element consists of two independent, three phase induction regulators, electrically identical, with the rotors on a common shaft. The voltage outputs of the independent stators are equal in magnitude and are varied in phase angle by changing the position of the rotor, as is usual in a 3 phase induction regulator. The two regulator units are mounted mechanically opposite to each other so that turning the rotor shaft in one direction effects a clockwise rotation of the one

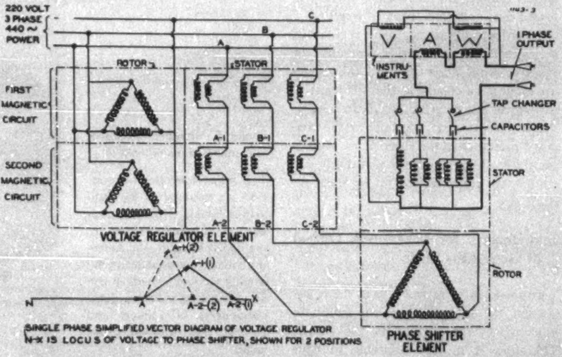

Figure 3. Calculator-generator unit

Actual system sources of synchronous emf are represented by a combination of voltage regulator and phase shifter. Independent control of voltage and phase angle is achieved by a combination of a double-unit three-phase regulator connected to a phase shifter. The voltage regulator has two electrically identical units physically arranged so that adjustment of the rotors does not shift the phase angle of the output to the phase shifter

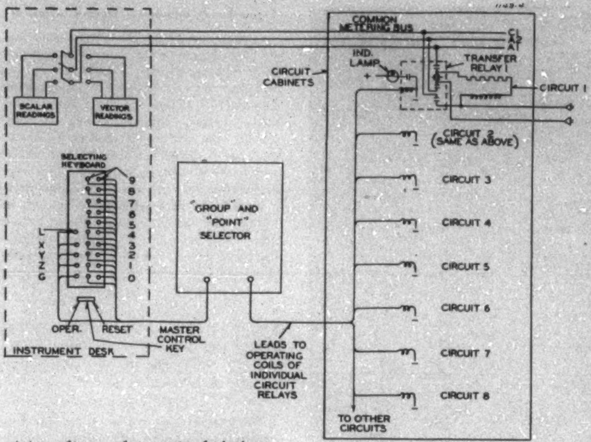

Figure 4. Schematic arrangement of circuit selector for a-c network calculator

The circuit selector consists of the keyboard, a "group" and "point" assembly of telephone-type supervisory relays, and one circuit transfer relay for each circuit. Only 25 keys are required for the selection of any of the present calculator circuits as well as for future additions up to a total of 599 circuits. To select a circuit three keys are pushed, one in each vertical row, and then the control key is thrown to the "operating" position. This closes the selected metering relay located directly behind the respective drawer section in the circuit cabinet. Closing the relay connects the circuit into the metering bus. A guard relay is provided which prevents the selection of any other circuit until the control key is thrown to the "reset" position

stator voltage and a counterclockwise rotation of the other. The two stator windings are connected in series so that the changes in phase angle neutralize each other thus giving a voltage which is always in phase with the supply voltage. This induced voltage is added directly to the supply voltage, thus giving a scalar adjustment of voltage. As shown in the single phase vector diagram of figure 3 the voltage *NA* is the single phase line-to-neutral voltage of the power supply, voltages *A* to *A*-1 and *A*-1 to *A*-2 are the voltages induced in the stators. The output voltage *N* to *A*-2 is adjustable from 0 to twice *NA* in magnitude but always along the phase position as indicated by the dotted line *N-X*. The three phase output of the regulator is then put into the rotor of the phase shifter. A single phase output is taken from the stator for use in the network. Turning the rotor of the phase shifter changes the phase angle of the generator unit voltage as may be required.

In order to obtain negligible regulation, series capacitors are used to neutralize the reactive drop, while the units themselves are made large enough so that the resistive drop gives less than 2% regulation as previously mentioned. Because of the constant reactance of the three phase voltage regulator, the reactance is accurately and completely compensated for by fixed capacitance.

Instruments for Measuring Output of Generator Units

In a calculator network, as in the power system, the adjustment of one generator unit affects the current in the others. Therefore, it is very desirable to have simultaneous indications of the outputs of all the generator units. Since the output can be completely defined in terms of voltage, scalar current, and watts, a voltmeter, and ammeter, and a wattmeter are supplied. Each instrument is equipped with a red marker which can be set to indicate the desired output of the unit. Adjustments of the phase shifters and voltage regulators are made until the indicating pointers line up with the markers. The ammeter is used in short circuit studies and in obtaining equivalent networks. A wattmeter reversing switch is provided to obtain indication of reverse power. A voltage-selecting switch is also provided so that either terminal or internal values of the generator unit may be obtained if the associated impedance unit is set proportional to the internal reactance of the machine being represented.

Circuit Elements

As indicated in figure 1, actual system transformers, transmission and distribution lines, reactors, and capacitors are represented on the calculator by various combinations of resistor-reactor, capacitor, auto-transformer, and mutual reactor circuits. The circuit elements are so designed that for all normal problems there is no necessity for consulting calibration curves to compensate for reactance of resistors, or resistance of reactors.

The value of any resistor or reactor tap is within plus or minus $1^1/_2$% of the setting. The resistors are non-inductive and have negligible (−.00002) temperature coefficient. The iron cores of the reactors have large air gaps so that the permeability of the magnetic circuit is constant

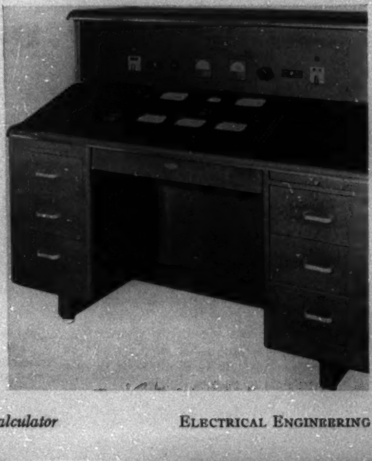

Figure 5. Master instrument and control desk

The motor-generator set controls are mounted on the small vertical panel. Two independent sets of master instruments, the circuit selector, and metering controls are mounted on the sloping sections. Readings can be obtained of scalar or vector components of voltages and currents, watts, vars, and phase angle

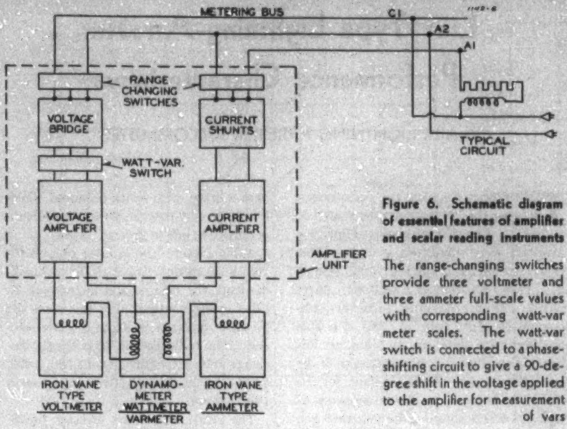

Figure 6. Schematic diagram of essential features of amplifier and scalar reading instruments

The range-changing switches provide three voltmeter and three ammeter full-scale values with corresponding watt-var meter scales. The watt-var switch is connected to a phase-shifting circuit to give a 90-degree shift in the voltage applied to the amplifier for measurement of vars

and hence the reactance is constant throughout the normal range of current. The reactors are designed to keep the resistance to such a low value that its effect can be neglected. This is achieved through the use of "U"-shaped Hypernik punchings (Hypernik having very low core loss at the density used) and by arranging the coils so that the ampere turns are divided equally across the two air gaps. Whenever it is deemed necessary to subtract the resistance of the reactor from the resistance component of the impedance representing an actual circuit element, an average value of 4% of the reactance value can be used.

Ratings

The range of values for the various classes of circuits is shown in the accompanying table.

All circuits are designed for operation at 220 volts, the normal base being 100. Reactors are capable of carrying 3 amperes (300% of normal).

Load and Load Adjuster Units

System loads are simulated on the calculator by means of series or parallel connection of the resistance and reactance elements of the load circuit. The value of this impedance is calculated from the desired kv-a. power factor and voltage at the load bus, using the following formulas:

Series connection

$$R=\frac{K(E')^2}{\text{Kv-a.}}\cos\phi$$

$$X=\frac{K(E')^2}{\text{Kv-a.}}\sin\phi$$

or *parallel connection*

$$R=\frac{K(E')^2}{\text{Kw.}}$$

$$X=\frac{K(E')^2}{\text{R-Kv-a.}}$$

Where K is the power multiplier, or the factor by which the volt-amperes in the calculator circuits are multiplied to give the kilovolt-amperes in the corresponding actual system circuit; E' is the calculator voltage at the load bus; Kv-a. is the 3 phase kilovolt-ampere load desired; and ϕ is the power factor angle.

Range of Circuit Elements

(Since Normal Base is 100 Volts—1 Ampere, 100 Ohms=100%)

Element	Range	
Line impedance (series) $R+JX$	R 0–39 ohms X 0–300 ohms	0 to 100 in 0.2 ohm steps 100 to 399 in 1 ohm steps 1 to 300 in smooth variation*
Load impedance (series or parallel) $R+JX$	R 0–3,990 ohms X 0–2,400 ohms	0 to 1,000 in 2 ohms steps 1,000 to 3,990 in 10 ohm steps 1 to 2,400 in smooth variation*
Capacitance	C 0–4.10 mfd.	In 0.01 mfd. steps
Auto-transformer	%80 to 124.5	In 0.5% steps
Mutual reactors	Ratio 1 to 1†	

*Reactance values are obtained by a combination of fixed air-gap reactors in series with a variable air-gap reactor.

†Value of coupling is determined by impedance circuit connected across either primary or secondary.

Generally, the systems which are set up on the calculator contain several load points and more than one generator; and the voltages at the load busses are not known. For such cases, an assumed value of E' is used in the formula to determine the calculator values of resistance and reactance of the load circuits.

To adjust the values thus obtained to the desired values of load without changing impedances, a simple load adjuster is used. This consists of an auto-transformer with taps corresponding to 1% of the circuit voltage. This auto-transformer is connected ahead of and in series with the load impedance. By means of a reversing switch, the auto-transformer is inserted to increase or reduce the applied voltage. The load adjuster is set by selecting the proper tap and switch position so that the voltage applied to the impedance equals the assumed value. For example, if the assumed value was 100 volts and the voltage read at the load bus was 105, the auto-transformer tap would be set at 5%, and the reversing switch set to lower the voltage. The resistance and reactance do not have to be changed, yet the volt-ampere load taken at the load terminal is equal to the desired value because of the transformer action. The use of these load adjusters is a distinct advance in calculator manipulation.

Circuit Metering

A set of master instruments is provided for determining the electrical conditions of the network. There have been several stages in the development of means for connecting the circuits to the master instruments. The original design utilized manual plugging of an instrument switch associated with each circuit. Later, provision was made for metering a few selected circuits from pushbuttons on the master control desk. These operated transfer relays, one for each circuit. Such an arrangement for all the circuits on a large calculator would require excessive space on the operator's desk and thus would be inconvenient to handle. One of the outstanding features of the new calculator is the use of a 25 pushbutton selector, arranged in a compact assembly like a comptometer keyboard. By pushing the buttons corresponding to the digits of the desired circuit any one of the several hundred circuits is quickly connected to the master instruments. Only one circuit can be connected at a time because of mechanical and electrical interlocks. Figure 4 shows the schematic diagram for this equipment. This simple circuit selector saves valuable space and facilitates circuit connection.

The meter desk shown in figure 5 is the latest development in such equipment, being the result of experience with both horizontally and vertically mounted meters for this application. Having the circuit metering instruments and controls and the writing space on the same sloping plane has been found to eliminate fatigue and to facilitate the recording of readings.

Another distinct advantage of the new desk design is that sufficient space convenient to the operator is made available for using two independent sets of instruments. One set is designed for maximum convenience in obtaining scalar quantities by means of an ammeter, a voltmeter, and a watt-var meter. The second set of master instruments for vector readings, comprises a voltmeter and an ammeter. These, in conjunction with an instrument phase shifter, permit obtaining component values of current and voltage as well as associated phase angle relations. The significant factors in the given problem determine the selection of instruments. For example, the scalar instruments are generally chosen for the ordinary voltage regulation problem; while for stability problems, and certain relay studies where phase-angle and component quantities are desired, the vector instruments are better suited.

All of the master instruments are rugged high torque, instruments with knife edge pointers. The scales are approximately 5 inches long and very uniform so that with a minimum number of full scale values the entire range of electrical quantities can be accurately and quickly obtained. The instruments have a guaranteed accuracy of $^1/_2$ of 1% of full scale for any reading. In order to obtain better results on voltage regulation studies, the voltmeters are calibrated for 100% accuracy at the normal voltage values used in these studies.

Scalar-Type Instruments, Watt-Var Meter, and Thermionic Amplifier

The instruments provided for direct measurement of scalar current, scalar voltage, and watts or vars are connected into the network through a thermionic amplifier which is so designed that the energy taken from the calculator network is negligible. The schematic diagram is shown in figure 6. The amplifier is a negative feed-back type (current feed-back), so that the calibration is independent of temperature changes in the instrument, tube characteristics, and supply voltage variations.[6,8]

Vector Instruments

The vector instruments for measuring component values of current and voltage with respect to any reference or scalar values and relative phase angle are of the dynamometer type. Field coils in these instruments are energized from a phase shifter so that the instrument burden on the calculator network is negligible. The complete description of this scheme has been published previously.[3]

Conclusion

The modern A.-C. network calculator has so improved the technique of operation that little time or effort is required to set up, adjust, and take readings. Errors due to operator's fatigue are practically eliminated. More studies can be made in a given length of time. These benefits are of maximum significance during a period such as the present, when time is the most important factor in power system planning.

Line-Type Lightning-Arrester Performance Characteristics

AIEE LIGHTNING ARRESTER SUBCOMMITTEE

THIS report contains the performance data for the line type arresters rated 20 to 73 kv. The characteristics of line type arresters were submitted as a committee report in AIEE Transactions, volume 57, 1938 (November section), pages 661–2. The lightning arrester subcommittee felt that it was desirable to bring the data up to date at this time; also, that the characteristics of the arresters should be made available for discharge currents up to 20,000 amperes, as well as a curve showing the volt-time gap breakdown characteristics.

The data in this report were obtained from the data submitted by the manufacturers for their respective products. The average values in the report are the average of the manufacturer's average values.

The tolerance from average curve was found to be ±25% for arrester breakdown and ±20% for arrester *IR* discharge voltage.

The arresters covered in this report have a sixty cycle spark potential which is at least 1.5 times the arrester maximum permissible line-to-ground rating.

Table I shows the arrester breakdown values taken on a wave rising to breakdown at the rate of 100 kv/ms per 12 kv of arrester rating. For this wave the breakdown occurs at about 0.4 microsecond. The table also includes the *IR* discharge voltage for currents of 1,500, 3,000, 5,000, 10,000, and 20,000 amperes on a 10×20 wave.

The relation between arrester breakdown voltage for the several voltage ratings is shown in figure 1. The tolerances are also shown.

Paper 41-138, recommended by the AIEE committee on protective devices, and presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941. Manuscript submitted April 20, 1941; made available for preprinting July 2, 1941.

Voltage 10×20
Average values
Tolerance ±20 per cent

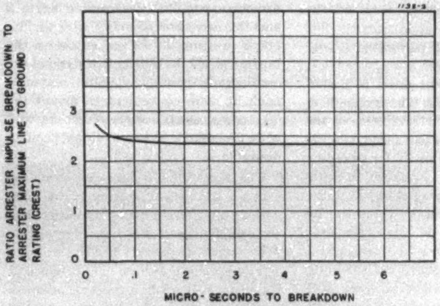

Figure 2. Volt-time impulse-gap breakdown

The arrester volt-time breakdown characteristics are shown in figure 2. The breakdown values are given for times as small as $^1/_4$ microsecond and as great as 6 microseconds.

Arrester average *IR* discharge voltages are shown for all ratings at currents of 1,500, 3,000, 5,000, 10,000, and 20,000 amperes, 10×20 wave.

The data in this report will assist in the evaluation on a volt-time basis of the margin between the arrester performance and the insulation to be protected. Consideration must also be given in such evaluations to other factors including rate of voltage rise, distance (circuit feet) between the arrester and the apparatus, ground resistance, selectivity required.

A Cathode-Ray Oscillograph With Rotating-Drum Camera

E. G. DOWNIE
ASSOCIATE AIEE

THE equipment and methods to be described have been developed to meet a need for a simple and effective means of photographing recurring or non-recurring waves viewed on the screen of the cathode ray oscillograph. The recording camera is simple and easy to operate and very economical of film. The recording method also provides for photographing any number of voltage or current waves, and later comparing the phase angles of all the waves. This oscillograph is designed primarily for slow speed work, particularly on waves of 60 cycle fundamental frequency, and in this feature is entirely different from the high speed cathode ray oscillograph described by Kuehni and Ramo.[1]

The cathode ray tube used is a high vacuum, seven inch screen tube. The screen is of the "fast" type with a highly actinic spot of short persistence. A suitable enclosing sheet steel case and a separately boxed 3,000 volt d-c power supply unit were constructed. When the equipment is used for visual work, sweep voltage is applied to one pair of deflecting plates from an independent sweep circuit.

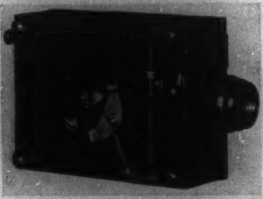

Figure 1. Camera arranged for spring operation of drum

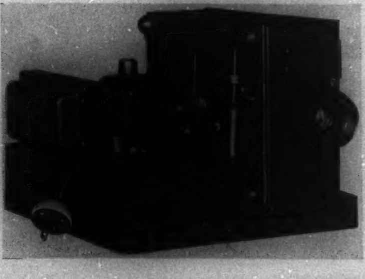

Figure 2. Camera with synchronous motor drive

Permanent records of the screen images are obtained with a revolving drum camera focused on the screen. No sweep voltage is used so that the wave to be photographed appears as a single straight line on the screen; with the moving film providing the time axis. The camera consists of an $8^{1}/_{2}$ in. by $6^{1}/_{2}$ in. by 3 in. sheet steel box with light tight cover, a $5^{1}/_{2}$ in. diameter drum (taking 35 mm. film) mounted on a single ball bearing with shaft and control arm extending out of box; and a Biotar lens of 50 mm. focal length, *F*1.4 aperture. In use, the camera is spaced approximately 15 in. from the tube screen by a light tight tapered sheet steel shield. This spacing is such that the image of the screen approximately fills the usable width of the perforated 35 mm. film.

Rotation of the film drum is accomplished by two methods. The first method, involving only a single revolution of the drum, is used for low film speed, and has been found especially useful for recording 60 cycle wave forms. As shown in figure 1, the drum control lever is locked at the beginning and end of a revolution by spring catches. At the start, the lever is given a short impulse by a spring tensioned lever, when released from the first spring catch. The ball bearing mounted drum has sufficient inertia to make the revolution at practically constant speed, and at the end is stopped by the rubber padded bolt and held by the second spring catch. Drum speed is controlled by changing the impulse lever spring tension and is fairly constant at a fixed setting during successive exposures. The film exposure is made by opening a simple shutter at the start of the revolution and closing it at the end. Transients may be initiated at about one third of the drum revolution by the small toggle switch operated by the drum control lever. The switch is double throw, so it may be used to open or close a circuit, as may be required.

The second method of drum operation is by synchronous motor drive. Continuous rotation is permitted by removing the stop and spring catch assembly. The motor most frequently used was made from a synchronous phonograph motor by special gearing, to give a speed of 550 rpm. The resulting film speed is 13.6 ft. per sec. and the span of one cycle of a 60 cycle wave is 2.72 in. This is a convenient speed for 60 cycle phase angle measurements to be later described. Exposure of the film in this case is made by opening of the shutter during a single revolution, or $^{1}/_{10}$ second. Synchronization of the shutter with the drum is desirable but not absolutely necessary. The motor and camera assembly are shown in figure 2 and the complete assembly with oscillograph in figure 3. In use, of course the tapered shield fits tightly in the end of the oscillograph case. Available materials made it more convenient to mount the $^{1}/_{10}$ second shutter in the shield, instead of on the camera proper, as would be more desirable.

The film drum is removed from the case for convenient loading of the film. The 35 mm. film (either unperforated or the standard perforated motion picture film) is cut to proper length, wrapped tightly around the drum, and fastened at the ends with a small piece of adhesive tape. Loading must of course be done in a dark room. Film used is the most sensitive obtainable, Eastman Super-XX, or Agfa Ultra-Speed Panchromatic; and is developed to high contrast in a "maximum energy" developer such as formula D-82. Such extreme sensitivity is not needed for low frequency waves, but is required when high frequency surges are to be recorded. In practice the intensity of the oscillograph beam is the only factor changed to provide proper exposure at different frequencies. Too high in-

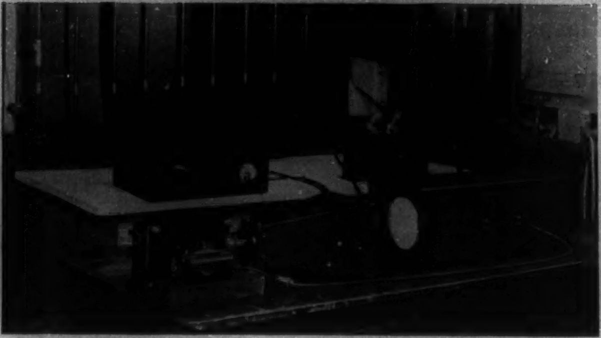

Figure 3. Camera and oscillograph assembly

tensity beam at low frequencies will cause screen retention and blurring on the recording film. The film may conveniently be developed, four lengths at a time, in a small tank such as used for 36 exposure miniature camera film.

The synchronous motor drive provides a uniform time axis, for comparison of successive films. A reference point of phase position on each film then, would also permit comparison of phase angle of waves on successive films. This reference point in each half cycle is obtained by superimposing a small peaked voltage on the wave being studied. This is provided by a coil mounted outside the tube carrying current from a special transformer[8] which produces a small peaked voltage of approximately 5 degrees duration in each half cycle. The magnetic field from the coil deflects the cathode beam in conjunction with the electrostatic field from the internal plates. This transformer must be excited from the same source as the waves being recorded. The voltage shows up on the film as a peak or ripple superimposed on the original wave. It can be easily identified on any except very irregular high frequency waves.

Adjustment of the phase position of the peaked voltage is often desirable to place the peak where it will least interfere and be easiest distinguished on the test wave. Some models of the peaked voltage transformer provide a limited phase shift by a variable resistance in one part of a divided primary winding. A three-phase original voltage source can also be utilized to provide a suitable phase position.

A series of films taken by the above method may be analyzed as shown in figure 4. The films are first arranged in careful register, with respect to the peaked voltage, on a printing frame and a negative film copy made from them. Enlarged prints are then made from this negative, giving black lines on a white background. The vertical line drawn through the peaks is the phase reference, from which measurements may be made on the various waves. Figure 4 shows oscillograms taken of luminous tube transformer secondary voltages, to show the phase relation between no load and various tubing load conditions. This is not conveniently done with a mechanical oscillograph, since only the cathode ray oscillograph, through a capacitance voltage divider, gives a true indication of luminous tube voltages.

In recording an unknown or mixed frequency wave, such as produced by

High-Voltage D-C Flashover of Solid Insulators in Compressed Nitrogen

JOHN G. TRUMP
ASSOCIATE AIEE

JAMES ANDRIAS
ASSOCIATE AIEE

HIGH-voltage apparatus insulated by compressed gas requires the use of solid insulating supports. It is generally recognized that even in a uniform field the flashover voltage of such solid insulation is considerably lower than for the gas-filled gap of equal length. An increase in the allowable gradient along such insulators would in general result in a reduction in the size, weight, and cost of gas-insulated apparatus, and must therefore be considered an important and fundamental objective of high-voltage engineering. It is probable that the flashover strength of solid insulators may be brought closer to that of the gases in which they are immersed, or to their inherent volume breakdown strength, through a better understanding of the influence on insulator flashover of such factors as material, surface condition, corrugations, and gas pressure.

Most of the scant literature on this subject is restricted to relatively low alternating voltages, small samples of solid dielectrics, or to special insulator shapes in non-uniform fields.[1] Reher studied the flashover of plain cylinders of ebonite, paraffin, and porcelain in dry air at pressures up to 15 atmospheres, using alternating voltages up to 140 kv maximum.[2] Goldman and Wul[3] have investigated the flashover of plain ebonite cylinders in nitrogen with alternating voltages up to 125 kv maximum and pressures up to 20 atmospheres. The present paper reports d-c flashover values up to 250 kv across short cylindrical insulators placed in the uniform field between metallic electrodes. These studies were made on both plain and corrugated cylinders of three dissimilar insulating materials immersed in dry nitrogen at gauge pressures up to 400 lbs. per square inch.

Apparatus

The test insulators were mounted between six-inch-diameter steel electrodes supported within a 13-inch-diameter steel pressure chamber. One of these electrodes was fastened to the end of a high-voltage bushing capable of bringing into the tank voltages up to 500 kv; the other, to a movable support which was insulated from ground so that the pre-flashover currents could be measured. The electrode gap was of such shape that a substantially uniform field existed in the central gap area for all spacings up to $1^1/_2$ inches. Windows were provided in the tank so that the appearance of corona and flashover could be observed.

The voltage source was a 500-kv electrostatic generator of the Van de Graaff type. The voltage was measured by a special spiral-line, high-voltage resistor with an estimated error of less than 3 per cent. Dry commercial nitrogen, which is similar in its electrical properties to air and other permanent gases, was used in this work.

Test Pieces

Three types of solid-insulator materials known by the trade names, Lucite, Textolite, and Isolantite, were studied. Lucite is a polymerized methylmethacrylate which has properties of high dielectric strength and resistivity, homogeneity, and machinability, with moderate mechanical strength. Textolite (No. 2029) is a laminated plastic with a paper base bonded with a phenolic compound. This material has a high dielectric strength across laminations and a moderately high resistivity. These two materials have basic differences which influence their performance as insulators, and each may be regarded as representative of a large group of plastics which are useful as solid insulation in high-voltage applications. Lucite is homogeneous in the volume, has the high volume resistivity of 10^{15} ohm cm, and may be given a smooth, nearly optically perfect surface finish; while Textolite is laminated, has moderate sur-

[1] For all numbered references, see list at end of paper.

---

noise or vibration, a permanent timing record on the film is desirable. The superimposed peak is not distinguishable on such a wave. Another method of adding the timing record was devised and found to be quite satisfactory. A small hydrogen filled 110 volt incandescent light bulb is enclosed in a shield to emit a small spot of light, and placed at the edge of the tube screen. The filament of the hydrogen filled bulb, operated on 60 cycle alternating current, completely darkens every half cycle and makes a broken trace at the edge of the oscillographic film. A luminous gas bulb, of sufficient intensity to record on the film, could be used as well. A film recording vibration, with timing trace by this method, is shown in figure 5. The other items in figure 5 show a luminous tube voltage wave form and a "saw-tooth" sweep voltage. These were taken with the single revolution method of drum operation.

The oscillograph and camera equipment has been used in regular laboratory testing and developmental work during the past two years. In addition to the above mentioned application, they have been used in analysis of high frequency ripple in output of direct and alternating current generators; measurement of radio frequency surges in both windings of ignition, high potential testing, and luminous tube transformers during high and low side switching; and noise and vibration analysis of motors. Recently the equipment was transported 200 miles by automobile and returned with oscillograms of high potential testing voltages on an assembly line. It is clear that this type of oscillograph does not attempt to replace the mechanical oscillograph, the cathode ray oscillograph with single high speed condenser discharge sweep, or the newly developed multibeam cathode ray tube, but it has been found very useful in a class of work not well covered by any of these.

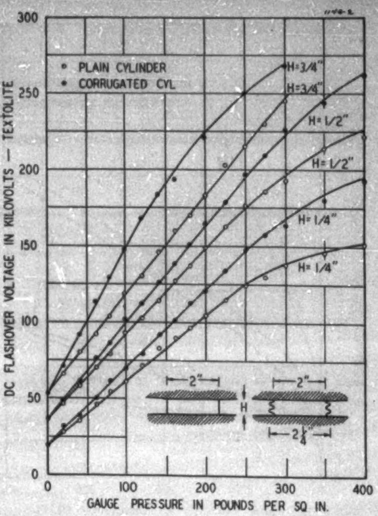

Figure 2(right). D-c flashover strength of Textolite cylinders immersed in dry nitrogen at high pressures. Uniform field

face resistivity and a volume resistivity of about 10^{11} ohm cm, and can readily be given only a moderately smooth surface finish. Isolantite is a porcelain ceramic which has magnesium silicate as its chief ingredient. This material, which may be considered as representative of most electrical porcelains in this application, has high surface resistivity and volume resistivity of about 10^{14} ohm cm, is uniform in the volume, and has the surface smoothness and mechanical properties characteristic of porcelains. The approximate dielectric constant of these materials in the order mentioned above is 4.2, 4.6, and 6.1.

The test insulators were circular in cross section so as to provide axial symmetry, and were $^1/_4$, $^1/_2$, $^3/_4$, and 1 inch in length. The plain cylinders of Textolite and Isolantite were 2 inches in diameter, while those of Lucite were $1^1/_4$ inches in diameter. All of the corrugated pieces had four corrugations per inch, with a 2-inch root diameter for the Textolite and Isolantite, and a 1-inch root diameter for the Lucite. The laminations of the Textolite test pieces were perpendicular to the axis of the cylinders. The cylindrical surfaces of the Isolantite test pieces were glazed.

To ensure good electrical contact between the test insulators and the electrodes, the end surfaces of the former were carefully coated to within $^1/_{32}$ inch of the edges with a conducting graphite mixture. This method was found to be the best of the several means of securing end contact which were tried. To ensure a dry and clean surface condition, the specimens were cleaned with carbon tetrachloride and stored for several days in an atmosphere in which the relative humidity was maintained at less than one percent.

Test Results

The d-c voltage which the insulators could withstand was in every case limited by surface flashover rather than volume breakdown through the material. Figure 1 gives the d-c flashover of plain and corrugated cylinders of Lucite placed in the uniform field between metal electrodes in compressed nitrogen. It is to be noted that with this homogeneous and high-resistivity material the advantage of corrugations becomes considerable only at the higher pressures. The flashover voltages increase linearly with pressure at first, and then more slowly. The flashover values increase nearly directly with the length. Figures 2 and 3 give similar data for Textolite and Isolantite. At the higher pressures Textolite shows a considerably lower flashover voltage than Lucite. For reasons that are discussed below, the influence of corrugations in raising the flashover voltage is pronounced. The flashover values obtained with plain cylinders of Isolantite were normal at atmospheric pressure but increased relatively slowly with pressure. This material was markedly benefited by corrugations.

In figure 4 the flashover strengths of $^1/_2$-inch corrugated cylinders of these three materials between flat electrodes in compressed nitrogen are compared, over the same pressure range, with the breakdown strength of the gap alone. At the lower pressures the flashover strength of corrugated Lucite is nearly the same as that of the gas gap, the departure increasing more rapidly the higher the pressure. At 100 lbs. per square inch the relative flashover strengths of the Lucite, Textolite, and Isolantite cylinders, on the basis of 100 percent strength for the nitrogen gap, were 80 percent, 48 percent, and 40 percent, respectively.

Influence of Surface Irregularities on Flashover

The fact that surface flashover limits the voltage which can be applied to a solid insulator placed between plane parallel electrodes in a compressed gas, may be explained by physical and electrical surface irregularities and by the field-distorting influence of surface-bound space charges. Since solid insulators usually possess dielectric constants in the range from 2 to 6, and are immersed in a compressed gas whose dielectric constant is substantially unity, the effect of physical irregularities—such as a depression—is to distort the otherwise uniform electric field and to increase the electric field intensity on the insulation of the lowest dielectric constant. Figure 5*a*

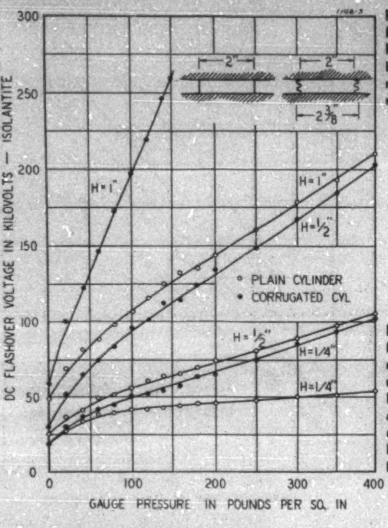

Figure 3 (left). D-c flashover strength of Isolantite cylinders immersed in dry nitrogen at high pressures. Uniform field

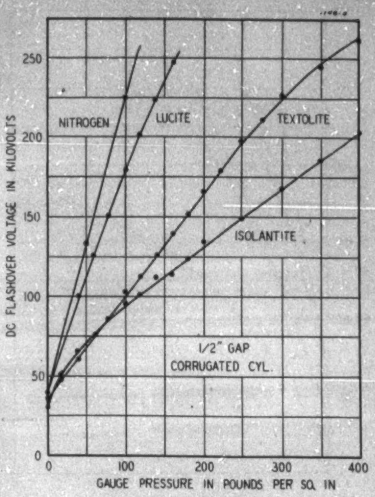

Figure 4 (right). D-c flashover strength of nitrogen and of corrugated cylinders of Lucite, Textolite, and Isolantite immersed in nitrogen at high pressures. Uniform field, 1/2-inch gap

shows the equipotential lines and lines of electric flux in the region of an ideal insulator placed in the uniform electric field between parallel electrodes. Figure 5*b* shows the concentration and distortion of the field caused by a depression in such an insulator. The stress in the region of this depression is nearly *k* times the average stress of the gaseous medium where *k* is the dielectric constant of the solid. Thus, although the average gradient may be substantially less than that required for the breakdown of the gas, the gradient in the region of the irregularity may be sufficient for local ionization. Although the space charge which builds up on the surface of such a defect tends to correct the unfavorable field situation, this local ionized condition of the gas and surface will lead to flashover at a lower voltage than would otherwise be required. This self-healing by ionization in the vicinity of defects in solid insulation is much less effective when alternating potentials are applied, since in this case energy must be expended continuously in the overstressed region. The discussion below is based on applied constant potentials only and should not be assumed to hold in the case of alternating potentials.

Influence of Surface Leakage

Another factor entering into the d-c flashover strength of insulators is the modification of the potential distribution along the insulator surface by leakage. If the surface and volume of the insulator have a uniform leakage resistance, the gradient along the surface is constant and the potential distribution is ideal. Such uniformity of leakage is difficult to obtain, however, particularly when high resistivities such as that of solid insulators are involved. Factors of two in the resistivity of dry, carefully conditioned surfaces of the same insulating material are not uncommon, and the influence of moisture or surface contamination may cause local variations of the resistivity differing from the average by several orders of magnitude. While such nonuniform surface leakage may be modified in some cases by the more uniform leakage through the volume of the insulator, it has the effect of imposing a less favorable distribution of potential along the insulator surface. Local ionization and breakdown of the surrounding gas will originate in the regions of high field intensity, and complete flashover of the insulator will take place at a lower voltage than would be required under uniform leakage conditions.

Effect of Surface-Bound Charges

Again, distortion of the electric field in the vicinity of the surface of an insulator may result from charge accumulations on the surface. This effect should be most pronounced on insulators in which the surface and volume leakage is very small. Such surface-bound charges may be produced by sparking or by corona from an electrode projection. It was observed, in the case of the Isolantite insulators, that at the higher pressures the voltage diminished with repeated flashover to about 50 percent of the normal value, but that the normal voltage was recovered after a lapse of 15 to 30 minutes. This effect was apparently due to the accumulation of surface-bound space charges which distort the electric field. The charge could also be caused to leak off more rapidly by reducing the gas pressure to atmospheric pressure. This effect was not observed with Lucite, although Lucite has even higher resistivity than Isolantite. This is probably because considerable corona preceded flashover in the case of Isolantite, due to the relatively poor end conditions mentioned below. A corresponding space-charge effect has been observed in porcelain high-voltage x-ray tubes. When the inside porcelain wall of such a tube is insufficiently shielded, charge accumulations may occur on the porcelain because of secondary emission. Such an accumulation may displace the electron beam, and this displacement may persist for long periods of time. By introducing air, so as to change from vacuum insulation to a relatively conducting state, this bound charge is quickly removed.

End Effects

A cause of lower flashover voltage can often be found in the improper contact between the solid insulation and the metal electrodes between which it is mounted. It was ascertained that the low flashover voltage of the Isolantite, for example, could be ascribed largely to this condition. As illustrated in figure 5*c*, the ends of these cylinders fitted imperfectly against the flat electrodes, leaving small wedge-shaped gas-filled gaps between electrode and insulator in which ionization readily occurred in the manner described above. This ionization, which may show as a continuous and visible discharge, both lowers the breakdown strength of the gas and distorts the electric field around the insulator by surface-bound charges. In order to confirm this cause of lower flashover, the ends of one of the Isolantite cylinders were reground to secure an improved contact with the electrodes. Though contact was still not ideal, this procedure increased the flashover values by about 20 percent. This difficulty was not observed with either Lucite or Textolite, since these materials could be machined quite accurately, and since their plastic nature insured excellent contact at the electrode-insulator boundaries. The influence of end contact must be regarded as of particular importance because ionization in this region can be supplied with unlimited amounts of power from the electrodes.

Effect of Corrugations on Insulator Flashover

It can be seen from figure 5*d* that the electric field is distorted in the vicinity of corrugations and that the electric field intensity acting on the gas between corrugations is materially higher than average because of the interposition of material of relatively high dielectric constant. It is to be noted, however, that this field distortion is a not-altogether-unfavorable effect, and that the increase in field strength between corrugations is by a factor of about 2 rather than *k*, as in the case of the wall defect of figure 5*b*.*

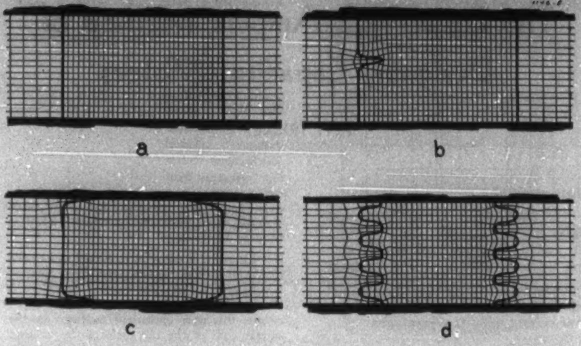

Figure 5. Field pictures of an ideal plain insulator in a uniform field (a), an insulator with a wall defect (b), an insulator with unfavorable end conditions (c), an ideal corrugated insulator (d)

In the case of plain insulators, the imminence of flashover is often revealed by a succession of faint gliding discharges originating on one electrode at the edge of the insulator and proceeding along the insulator surface toward the opposite electrode. On further increase in voltage, these surface gliding discharges increase in brilliance and length, and finally develop into complete and intense flashover. Corrugations, aside from increasing the surface length of the insulator, provide a shielding and localizing effect against such discharges which more than compensates for the field distortion and increased field intensity. The insulator surfaces on the side walls of the corrugations lie in a protected region of low intensity where the disturbing effect of discharges penetrates with difficulty. This is shown by the fact that the final flashover does not in general follow the contour of the corrugated insulator but glides over the tips of the corrugations and leaps across the gas gap between the corrugations.

The net effect of corrugations is to establish longitudinally along the insulator surface regions of alternately high and low field intensity which tend to localize the influence of surface defects, poor end contact, and space charge, and which interrupt the progress of gliding discharges. Corrugations, accordingly, should be expected to play the greatest role in those cases in which most of these conditions exist. The flashover strength of the Isolantite was markedly increased by corrugations, as can be seen from figure 3. In this case, local ionization at the ends caused a surface-bound charge to appear on the nearest corrugation, which reduced the tendency toward further ionization leading to flashover. In the case of Lucite these adverse factors were not present to any considerable extent, so that little advantage from corrugations was obtained until the higher pressures and gradients, at which all influences become more important and critical. It should, however, prove advantageous in general to employ corrugations in all practical applications of solid insulators in compressed gases, since—even with favorable initial conditions—it is probable that imperfections in the insulator surface, non-uniform leakage, or surface-bound charge arising from projections on the electrode may appear in time.

There is considerable tendency in the design of corrugated insulators for use in compressed gas or in high vacuum to have the maximum diameter at the insulator ends. This is intended to avoid the higher gradient which would be found immediately adjacent to the electrode, were the insulator to terminate in the root diameter. It is to be pointed out, however, that very small defects or crevices in the contact will result in local ionizing gradients, and that when this condition exists on the large-diameter ends, the ensuing gliding discharges may proceed from the fault toward the opposite electrode with little opposition. It appears preferable to terminate the insulator in the root diameter, as shown in figure 5*d*, in order that the nearest corrugation may act as a space-charge shield.

Conclusion

The d-c flashover strength of certain solid insulators in compressed gases is less than that of a corresponding gas-

---

*If a layer of gas of thickness d_1 and a layer of solid insulation of thickness d_2 and dielectric constant K_2 are arranged in series between parallel electrodes, the electric field intensity acting on the gaseous portion of the gap may be shown to be $G = K_2V + (d_2 + K_2d_1)$ where V is the total applied voltage. If d_1 is small in comparison with d_2, the field intensity acting on the gas approaches K_2 times that which would exist in the gap if it contained gas alone. This approximates the situation in the case of an insulator having a narrow fissure or cleft, as in figure 5*b*, or one which has poor end contact, as in figure 5*c*. When the thickness of the two dissimilar dielectrics are equal, the field intensity on the gaseous gap is $2K_2V/(1+K_2)d$ where $d = d_1 + d_2$ or $2K_2/(1+K_2)$ times that of a completely gas-filled gap. This approximates the situation in the corrugated portion of an insulator, as in figure 5*d*. The field intensity in the gas is in all cases K_2 times greater than in the solid dielectric in series with it. This explanation assumes that the electric field is due to charges on the electrodes alone.

The Equal-Volt-Ampere Method of Designing Capacitor Motors

P. H. TRICKEY
MEMBER AIEE

Introduction

IN September 1932, the writer presented a method of designing capacitor motors, known as the "balanced" method. Since that time an improvement on that method has been devised which has certain definite advantages.

The Equal-Volt-Ampere Method

The "equal-volt-ampere" method is fundamentally based on the "balanced" method, and consists in departing from the balanced winding in a certain prescribed manner so that the essential features are obtained with a smaller capacitor. The steps are as follows:

1. The motor is calculated as a two phase motor with both phases the same as the main winding of the proposed motor.

2. Using the formulas of the "balanced" method, a balanced winding and capacitor are designed by balancing at the full load point. The performance of this motor is calculated by the balanced method. If the performance is satisfactory, and if the capacitor is not operating up to its rated voltage, an "equal-volt-ampere" winding may be designed.

3. Choosing a value of capacity to be used in the proposed motor (usually the nearest size to give a capacitor voltage slightly less than the rated volts of the capacitor), calculate the new capacitor voltage as the square root of the the ratio of the balance point microfarads to the proposed microfarads.

4. Since the phase angle between the winding voltages is practically 90°, the capacitor winding voltage is obtained as the square root of the difference of the squares of the new capacitor voltage and the line voltage.

5. The winding ratio "K" (which is the ratio of the effective capacitor winding conductors to the effective main winding conductors) is the ratio of the new capacitor winding volts to the line or main winding volts.

6. Calculate the new "K_a" from the ratio $K/K_a = a$ constant, which should be kept the same as in the original balanced motor

$$K_a = \frac{r_{1a}}{K r_{1m}}$$

where

r_{1a} = capacitor winding resistance
r_{1m} = main winding resistance

In other words, the weight of wire in the capacitor phase is kept the same.

7. Choose the capacitor winding turns and wire size to give the new values of K and K_a. The nearest wire size is usually close enough.

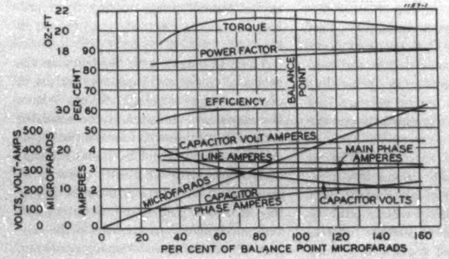

Figure 1. Effect of departure from the balance point while keeping approximately constant capacitor volt-amperes

Results of the Method

The determination of K and K_a completes the design of the "equal-volt-ampere" motor. Its performance will be almost identical to that of the "balanced" motor except for a slight decrease in power factor. This is best illustrated by the example below:

EXAMPLE MOTOR

1/4 hp 1140 rpm 115 volt 60 cycles three speed capacitor motor (speed change obtained by voltage control through regulator)

BALANCE POINT

$K = 1.746 \quad K_a = 2.50 \quad \text{mfd} = 18.85 \quad E_c = 231$

DESIRED CAPACITOR

Mfd = 12.6 (nominal value 12) rated at 330 volts

NEW CAPACITOR VOLTS

$$E_c' = 231\sqrt{\frac{18.85}{12.6}} = 283$$

NEW CAPACITOR WINDING VOLTS

$$E_a' = \sqrt{\overline{283}^2 - \overline{115}^2} = 259$$

NEW WINDING RATIO

$K' = 259/115 = 2.25$

NEW RESISTANCE RATIO

$K_a' = 2.50(2.25/1.746) = 3.22$

where

$$K = \frac{CKw_a}{CKw_m} = \frac{\text{effective series conductors in capacitor phase}}{\text{effective series conductors in main phase}}$$

$K_a = r_{1a}/Kr_{1m}$
r_{1a} = resistance of capacitor winding
r_{1m} = resistance of main winding
E_c = capacitor voltage
E_a = capacitor winding voltage

Paper 41-157, recommended by the AIEE committee on electrical machinery, and presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941. Manuscript submitted December 10, 1941; made available for preprinting August 12, 1941.

filled gap or than the puncture strength of the material. It is strongly influenced by surface defects, non-uniform surface leakage, surface-bound space charges, and by end conditions. The flashover strength benefits substantially by increase in the dielectric strength of the gas, and may approach the value of the free-gas gap when favorable field configurations, insulator materials, and proper surface and end conditions are included in the design.[4]

Figure 1 illustrates the effect on full load performance as the equal-volt-ampere winding departs from the balance winding with either more or less microfarads. (It should be noted at this point that while the method is called "equal-volt-ampere" there is a slight variation from exactly constant volt-amperes.)

Figure 2 illustrates the effect on the current vectors. With less than balanced point microfarads, the currents are less than 90° apart, and with more than balance point microfarads they are more than 90° apart.

Figure 3 shows the effect on starting torque and current.

Figure 4 shows the effect on the standstill vector diagram.

Figure 5 illustrating the effect on the speed-torque curve, shows that reduction of the microfarads by this method, results in a slight reduction in the maximum torque.

Figure 6 shows the effect on the no load performance which is a slight improvement with reduced microfarads.

Figure 7 shows the effect on the no load vector diagram.

Figure 8. Effect on starting conditions using windings chosen by the equal-volt-ampere method, but using starting microfarads to give maximum starting torque

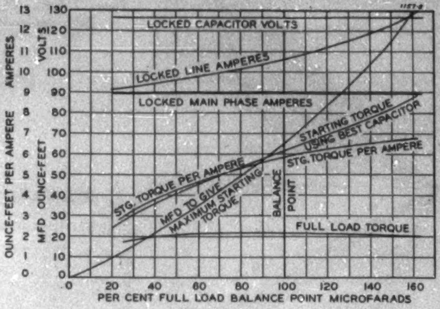

Figure 8 shows how this method affects the possible starting torque of a two value motor. It illustrates definitely that K can not be increased too far if it is necessary to obtain a high value of starting torque on the starting capacitor. In this case, the value of K and K_a would have to be determined by the necessary starting performance. Then the proper value of "equal-volt-ampere" running microfarads would have to be chosen to agree with these values of K and K_a.

Conclusions

The "equal-volt-ampere" method is a very simple and straightforward method of design. A motor is obtained which is well proportioned between performance and cost. All the necessary performance values of efficiency, speed, losses, and heating are obtained by relatively easy calculation formulas. That is, the performance is calculated by the "balanced" method, and used as the performance of the "equal-volt-ampere" motor.

The Inherent Overheating Protection of Single-Phase Motors

C. P. POTTER
FELLOW AIEE

THE problem of controlling and restricting the temperatures of motor windings, is of vital importance to the motor manufacturer, the motor user, and the general public. The motor manufacturer is anxious to have winding temperatures restricted to a safe value, so that his products may have customer acceptance. The motor user is interested in winding temperatures because they affect motor life and maintenance cost. The general public is not conscious of any interest in the matter, but is certainly affected in all cases where excessive temperatures result in fire hazards.

In the early days of the industry, motors did not have adequate protection against overheating, because suitable protective equipment was not available. Motor circuits were fused, but the fuses had to be large enough to accommodate the motor starting current and were, therefore, too large to properly restrict the running current or protect the windings. However, the lack of proper protection was partially offset by the special attention which was given motors by their owners and attendants.

The shortcomings of fuses led to the development of magnetic type relays provided with dash-pots, which retard the operation of the relays to such a point that they can be set to operate close to the full load current of the motor and still have enough time delay to allow the motor to start. These relays were incorporated in motor starting switches and in most cases provide adequate motor protection, but they have one undesirable characteristic. Their operation depends entirely on motor current, while the temperature of motor windings depends upon the room temperature as well as the motor current. A magnetic type relay which will protect a motor located in a room of normal temperature may therefore not protect the same motor when it is operated in a high ambient temperature.

Thermal type relays were the next development and are widely used today in motor starting switches. As the name indicates, these devices are actuated by the heating of a resistor, the temperature of which depends upon both the ambient temperature and the motor current. If the thermal characteristics of the resistor are like those of the motor, and if the relays have the same ambient temperature as the motor, thermal relays installed in starting switches should be entirely adequate for the protection of motor windings. The first of the above conditions is only approximated and the second one cannot always be met, therefore, starting switches provided with thermal relays must also be used with discrimination.

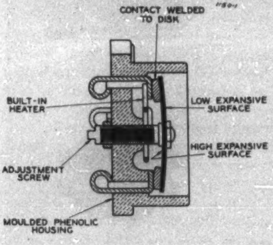

Figure 1. Cross-section of protector with heater coil

Inherent Overheating Protective Devices

Motor overheating is usually due to overloading, but may also be caused by too frequent starting, by foreign material becoming lodged in the motor openings, by installing the motor in a non-ventilated compartment, or in a number of similar ways, and such overheating cannot be prevented by any device which is mounted outside of the motor. Complete protection of motor windings can only be obtained by using thermal devices which are mounted inside the motor enclosure and which make use of resistors or "heater coils" through which the motor current passes. These devices are ordinarily known as "motor protectors" and are designated by the Underwriters' Laboratories as "Inherent Overheating Protective Devices."

Motor protectors have many modifications. When applied on certain types of service they are of the automatic reset type and as the name implies such a protector stops the motor when it reaches a dangerous temperature and automatically starts the motor when its temperature decreases to a safe value. For other types of service, protectors are of the manual reset type which must be reset by an attendant, who presumably inspects the installation to find out what caused the protector to open, before resetting it. Protectors which are used in motors 1 hp and smaller usually break the line current, thus eliminating the necessity of providing the ordinary overcurrent protection required by the Underwriters' Laboratories. Protectors which are used in motors larger than 1 hp do not ordinarily break the line current, but are connected in the pilot circuit of the magnetic switch which starts and stops the motor.

Motor protectors of the automatic reset type contain some sort of a thermostatic device such as a bimetallic disk or strip, which may be mounted adjacent to a heater coil through which the motor current flows. Figure 1 shows a cross-section of a device employing a heater coil, manufactured by the Spencer Thermostat Company. In other types the heater coil is omitted and the bimetallic strip acts as a resistor. A protector of the latter type manufactured by Cutler-Hammer, Inc., is shown in figure 2. In both cases the bimetallic elements carry contacts which are normally closed and which are connected in the motor line. These protectors are mounted inside the motor and when the temperature inside the motor reaches the maximum safe value, the bimetal snaps to its hot position, the contacts open, and the motor is disconnected from the line. When the temperature of the motor decreases sufficiently, the bimetal snaps back to its normal position and the motor is automatically started. Automatic reset protectors are used on motors which drive stokers, fans, blowers, pumps, small refrigerating outfits, etc. Automatic reset protectors are built in many styles, some of which are illustrated in figure 3.

Motor protectors of the manual reset type may employ a bimetallic element or they may have a thermal device of the

"solder pot" variety, mounted adjacent to a heater coil which carries the motor current. Figure 4 shows one of the former manufactured by the Micro Switch Corporation, while figure 5 illustrates a protector of the solder pot type manufactured by Cutler-Hammer, Inc. These protectors are actuated by the temperature inside the motor, but must be reset manually and cannot be permanently reset until the motor has cooled considerably. Manual reset protectors are used principally on motors which operate oil burners and other devices where it is desirable to investigate the cause of motor stoppage before restarting the motor.

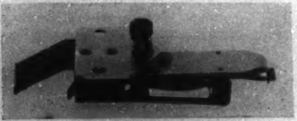

Figure 4. Manual reset protector with bimetallic element

Standard Tests on Motor Protectors

Several temperature tests are required by the Underwriters' Laboratories to determine the suitability of a protector for application on a motor. All temperatures are measured by means of thermocouples which are placed on the surface of the windings and enough thermocouples are used to be sure that the "hottest spot" is located. A series of temperature tests is made with the motor running at about 5% more than normal voltage and with gradually increasing loads, until the protector opens. A single test is made with the rotor stalled at about 5% more than normal voltage, and the protector is allowed to continually trip and reset until the temperature of the windings becomes constant. The object of these tests is to determine the maximum winding temperatures under these abnormal conditions, and restrict them to a safe value. If the temperatures thus taken are found to be reasonable, the application of the protector is considered satisfactory and it is assumed that the motor cannot be damaged no matter how it may be operated. It will be seen that tests have not been mentioned to determine the effect of high ambient temperatures, high or low voltage, high or low frequency, etc., and it would seem to be desirable to make such tests on a representative motor and determine whether motor protectors which have been applied in accordance with accepted rules, actually protect the motors on which they are installed, under all conditions of operation.

Special Tests on Motor Protectors

In order to obtain this information, special tests were made on a $^1/_3$ hp, 1,725 rpm, 110/220 volt, 60 cycle, single phase, repulsion start induction motor equipped with an automatic reset protector, both running and with the rotor locked, at voltages above and below the rated voltage, at frequencies above and below the rated frequency, at various ambient temperatures and with the motor ventilation progressively restricted and finally eliminated. The results of these tests are plotted in figures 6 to 14 inclusive and in order to avoid repetition the term "protector limited temperature" is used to describe the maximum winding temperature which exists when the protector trips. The protector limited temperature

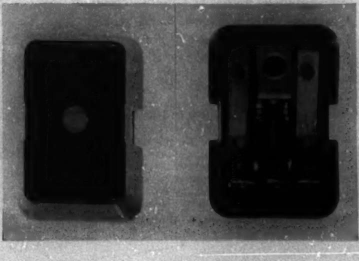

Figure 5. Manual reset protector with "solder-pot"

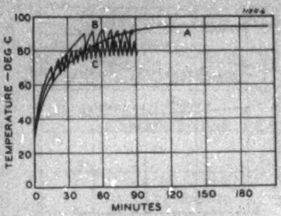

Figure 6. Winding temperature versus time

Normal voltage and frequency. $^{1}/_{3}$-horsepower repulsion-start induction motor with protector

Curve *A*: At maximum current permitted without interruption by protector

Curve *B*: At current 10 per cent greater than that of curve *A*

Curve *C*: At current 20 per cent greater than that of curve *A*

is usually much less than the ultimate temperature which would be reached without a protector.

Curve *A* in figure 6 shows the relation between time and winding temperature for the maximum current which the protector will allow the motor to carry continuously when it is operating at normal voltage and frequency. In this case the protector does not trip but any additional load would cause it to do so. The maximum winding temperature is 94°C, which is much lower than could be allowed. Curve *B* is plotted for a current 10% greater than the maximum current which the protector will carry continuously and curve *C* is plotted for a current 20% greater than the maximum current which the protector will carry continuously. In both these curves the protector trips and resets several times before the winding temperature reaches a constant value, and in both cases the protector limited temperature is less than the ultimate value for curve *A*.

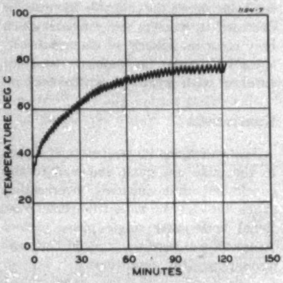

Figure 7. Winding temperature versus time

Rotor locked. Normal voltage and frequency. $^{1}/_{3}$-horsepower repulsion-start induction motor with protector

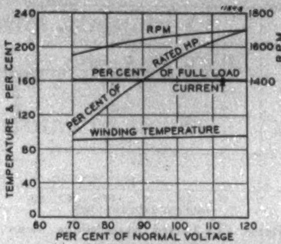

Figure 8. Motor characteristics versus voltage at maximum loads permitted by protector

Normal frequency. 28 degrees ambient. $^{1}/_{3}$-horsepower repulsion-start induction motor

Figure 7 shows the relation between time and protector limited temperature of the $^{1}/_{3}$ hp repulsion start induction motor at normal voltage and frequency with the rotor stalled. This is an abnormal condition, but is one which might exist in case of a mechanical defect in the motor or the machine which it drives. The protector trips and resets many times before the winding temperature reaches a constant value, which, however, is considerably less than for the running condition and is well within safe limits.

Tests were made with the motor operating at voltages above and below normal, to determine the effect of voltage on the winding temperatures permitted by the protector, and the results are shown in figure 8. It is interesting to note that under these conditions the protector is essentially a constant current device and allows the same current to flow at voltages from 70 to 120% of normal voltage. The protector limited temperatures at 70% voltage are slightly less, and at 120% voltage are slightly greater than the values shown in figure 6, but for all practical purposes the protector limited temperatures are not affected by the voltage. Motor loads and speeds are also plotted and as might be expected, they change quite rapidly with the voltage. It will be seen that if this motor is driving a compressor or pump and is considerably overloaded, it will be unable to carry the load at the lower voltages, because the protector will trip and disconnect the motor from the supply circuit.

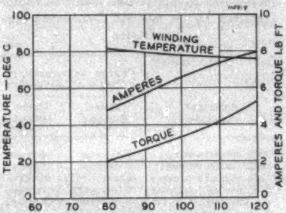

Figure 9. Locked characteristics versus voltage

Normal frequency. 31 degrees ambient. $^{1}/_{3}$-horsepower repulsion-start induction motor with protector

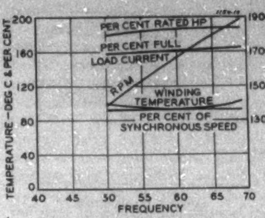

Figure 10. Motor characteristics versus frequency at maximum loads permitted by protector

Normal voltage. 28 degrees ambient. $^{1}/_{3}$-horsepower repulsion-start induction motor

Locked tests were also made at various voltages and the results are plotted in figure 9. In this case the locked current varies at about the same rate as the voltage, but the protector limited temperatures change very little as the voltage varies. This difference in protector operation between running and locked condition is due to the fact that when the motor is locked, the protector is essentially a constant temperature device and its operation depends almost entirely on the temperature of the heater coil which is adjacent to the bi-metal. Since the heater coil temperature and the winding temperature both depend on time and motor current, it logically follows that

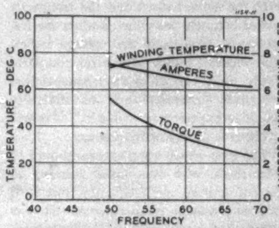

Figure 11. Locked characteristics versus frequency

Normal voltage. 31 degrees ambient. $^{1}/_{3}$-horsepower repulsion-start induction motor with protector

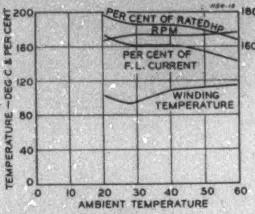

Figure 12. Motor characteristics versus ambient temperature at maximum loads permitted by protector

Normal voltage and frequency. $^1/_3$-horsepower repulsion-start induction motor

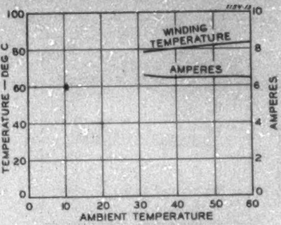

Figure 13. Locked characteristics versus ambient temperature

Normal voltage and frequency. $^1/_3$-horsepower repulsion-start induction motor with protector

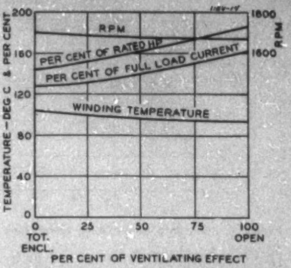

Figure 14. Motor characteristics versus ventilating effect at maximum loads permitted by protector

Normal voltage and frequency. 28 degrees ambient. $^1/_3$-horsepower induction motor

while the time required for the protector to trip a locked motor will vary with the current, the temperatures of the protector and the motor windings when the protector trips are not materially affected by the motor current, and, therefore, do not depend on the voltage applied to the motor terminals.

Figure 10 shows the effect of variations in frequency on the winding temperatures permitted by the protector, while the motor is running. The protector limited temperatures at high and low frequency are only slightly greater than they are at normal frequency and the motor protector takes care of frequency variations while the motor is running, quite satisfactorily. While this motor will carry the same horsepower load at a wide range in frequencies, it obviously cannot operate at frequencies much greater than the normal value because at the higher frequencies, the speed, horsepower, and motor current also increase and the protector will not be able to carry the increased current.

Figure 11 shows the effect of variations in frequency on the protector limited temperatures of the motor with the rotor locked. The operation of the protector with the rotor locked and the frequency varied is much the same as when the frequency is fixed and the voltage varies. The winding temperatures for comparatively wide variations in frequency are practically constant and no difficulty should be experienced with a locked motor at either high or low frequency.

The tests which are plotted in figure 12 were made with the motor running at normal voltage and frequency, but with various ambient temperatures. It was found that with ambient temperatures between 30 and 40°C the protector trips at a fixed value of current and the winding temperature increases at the same rate as the ambient. Above 40°C the protector trips at a smaller value of current and, therefore, the winding temperature does not increase as fast as the ambient. Below 30°C the protector trips at a higher value of current and the winding temperature increases in spite of the decreased ambient. It is evident that the protector limited temperature may increase considerably when the motor is running in a high ambient temperature.

Locked tests at various ambient temperatures were made and the results plotted in figure 13. In this case the winding temperatures do not change materially with the ambient, indicating that the protector trips when the temperature of the bi-metal reaches a definite value, and it makes little difference whether this temperature is produced by the heat of the motor or the surrounding air.

When open type motors are installed in locations where excessive amounts of foreign materials are present, the ventilating openings may become partially or even completely obstructed, and the motor may have an excessive temperature rise. Tests were made to determine whether a motor protector will take care of such a condition and the results are plotted in figure 14. With all the openings in the motor frame enclosed, the protector limited temperature increases 10° and the load which the motor can carry without tripping the protector is reduced 22%. It is unlikely that an open type motor will ever be completely enclosed either accidentally or deliberately; therefore, the probable increase in temperature resulting from foreign materials will be considerably less than 10°.

Variations in Winding Temperatures of a $^1/_3$-Horsepower Repulsion-Start Induction Motor Protected by an Inherent Overheating Protive Device

Abnormal Condition	Change in Temperature (Degrees Centigrade)	
	Motor Running	Motor Locked
120% normal voltage	2 increase	2 decrease
80% normal voltage	2 decrease	4 increase
117% normal frequency	Inoperative	1 decrease
83% normal frequency	6 increase	6 decrease
60° ambient	6 increase	3 increase
All ventilation eliminated	10 increase	No change

Summary

Motor protectors are selected and applied so that they restrict the motor winding temperature to specified values at normal voltage and frequency and a room temperature of 40°C. The accompanying table shows the probable increase (or decrease) in winding temperatures which may occur on account of abnormal voltages, frequencies, or ambient temperatures, or with restricted ventilation.

Conclusions

The variations in temperature shown in the table are small and lead to the conclusion that inherent overheating protective devices mounted inside fractional horsepower single phase motors completely protect them against all abnormal operating conditions.

Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits

Synopsis: This paper presents the results of an investigation made to determine and evaluate the effect of the factors affecting neutral instability of Y-grounded potential transformer circuits. The method used employs the medium of miniature system representation. The results therefore include the effect of saturation. The effects of the shape of the saturation curve, normal operating voltage, resistance of the winding, system capacitance, and impedance in the broken Δ secondary or across each phase are illustrated. Regions of instability are shown which should be avoided in applying Y-connected potential transformers as ground fault detectors. The analysis shows by means of oscillograms the conditions under which incorrect indications of faults may be obtained.

GROUNDED-NEUTRAL, Y-connected potential transformers with Y- or broken Δ-connected secondaries have been applied to three-phase circuits, the neutrals of which are temporarily or permanently ungrounded. The broken Δ secondary connection affords a means of ground fault detection, the voltage across the break in the Δ under such fault conditions being used to operate relays or otherwise indicate the presence of a ground fault.

In some cases, experience has shown that such a circuit is unstable. The phenomena involved have been described for limited ranges of circuit parameters.[1,2] One oscillographic investigation, however, describes the various conditions of instability in some detail.[3]

More recently other cases of difficulty with this type of circuit have been encountered. While correct indications of true faults were always obtained, indications of faults were sometimes obtained when no faults actually existed. These false indications sometimes resulted in higher than normal fault indicating voltages appearing across the break in the Δ secondary. This phenomenon was traced to the inherent instability of a circuit of this type when the amount of capacitive reactance to ground and the magnetizing reactance of the transformers involved are in certain relative proportions. As a consequence, a comprehensive analysis of the circuit was undertaken, using the miniature system transient analyzer,[4] which disclosed the regions of instability and methods of eliminating such instability. This paper presents the results of that investigation.

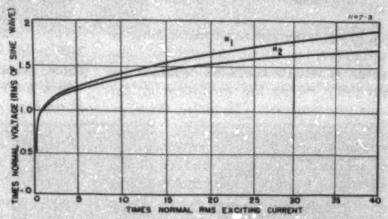

Figure 2. Transformer saturation curves used in the miniature system

1—Typical saturation curve

2—Curve having more saturation than curve 1

Basis of Study

The miniature system shown in figure 1 was selected as a basis for the study. The reactance of the sine wave generator was negligible compared with the external miniature system impedances. Thus balanced sinusoidal line-to-line voltages were applied at the transformer terminals. Consequently the phenomena were independent of positive sequence capacitance so that only zero sequence capacitive reactance, x_{co}, was involved.

Transformers used were single phase and their saturation characteristic is shown in figure 2. Curve #1 is representative of most transformers, and therefore was used throughout the study except for one case in which the #2 curve was used to indicate the effect of more abrupt saturation. The value of x_m is the ratio of normal line-to-neutral rms exciting volts to normal phase rms exciting amperes at normal frequency as defined by the saturation curves. The circuit can be completely defined by the ratio of x_{co}/x_m when the saturation curve used and the normal operating voltage are specified.

Provision was made to control the excitation of the miniature system sine wave set so that system voltage could be varied. It was not deemed practical to operate at voltages higher than normal, as indicated on the saturation curves, since in the system studied, a line-to-ground fault would result in extremely high magnetizing currents in the two unfaulted phases.

The study was made with and without load impedance in the break in the Δ. This is equivalent to putting load impedance across each phase in the case of Y-connected secondaries, the total ohmic resistance being the same in either case. Various impedances were used as burdens to determine the effect of impedance burden magnitude and power factor, both lagging and leading.

In practically all cases studied, the abnormal conditions were obtained by suddenly energizing the miniature system

or by applying and removing a fault to ground on one phase, although in some cases, instability could be obtained by gradually raising the excitation of the sine wave generator. However, the manner of obtaining the abnormal circuit conditions, as long as it is reasonable, is of secondary importance relative to the question as to whether abnormal behavior of the circuit is possible or not for given constants. The study is primarily concerned with answering this question.

It is of interest to point out in this connection that regions of possible abnormality may overlap with regions of possible normal circuit behavior. In other words, in regions of abnormal circuit behavior it is sometimes possible for the circuit to behave normally also, but it is never possible in a region designated as stable to have an abnormal circuit condition of the type under discussion in this paper.

It should also be pointed out that the regions of instability are regions where the abnormal conditions persist in the steady-state condition. It is possible for relatively long-time transients to exist near the border line in the stable region. These will die out eventually, however, and normal conditions will always be restored ultimately.

Discussion of Results

For a particular set of transformer characteristics the regions of neutral instability of the system shown in figure 1 are defined in terms of the ratio of system parameters x_{co}/x_m and of the system voltage E where E is the per unit system operating voltage. $E=1$ corresponds to system operating voltage of $E=1$ on the saturation curves of figure 2. In the application of potential transformers as a means of ground fault detection, it is customary to select a transformer rated line-to-line system voltage and operate it at system leg voltage; that is $E=0.58$. In some instances, however, circuits for which $E=1.0$ may be encountered if in a normally grounded system the Y grounded transformer bank is temporarily connected to an otherwise ungrounded circuit, or if single-phase transformers are connected line-to-neutral in a three-phase system which has an open circuit in the neutral at the system grounding point.

The data of figure 3 were obtained using a low-loss transformer with typical saturation characteristics, curve 1, of figure 2. The regions outlined are those in which instability may occur as the result of a shock, such as a line-to-ground fault applied and removed. Stable operation may be obtained within portions of the unstable regions if system voltage is gradually applied or if the Δ secondary is closed until normal steady-state conditions exist.

At each test value of x_{co}/x_m the system voltage was raised to a value corresponding to $E=1.0$. If the application and removal of a line-to-ground fault created an unstable condition as indicated by the presence of an abnormal voltage across the break in the Δ, the system voltage was then reduced to the boundary value at which the unstable Δ voltage collapsed.

As indicated on figure 3 neutral instability for this case may occur in one of three distinct modes, depending on the values of x_{co}/x_m and E. For values of x_{co}/x_m less than 0.01, no instability can occur for values of E less than 1.0. For values of x_{co}/x_m between 0.01 and 0.07, corresponding to relatively large values of zero sequence capacitance, the unstable voltage appearing across the broken delta is approximately of one-half normal frequency. Intermediate values of x_{co}/x_m (between 0.07 and 0.55) give rise to a fundamental frequency Δ voltage, and large values of x_{co}/x_m (between 0.55 and 2.8) give rise to a third harmonic Δ voltage.

The first of these three abnormal conditions is illustrated by the oscillograms in figure 4*a*. For the case $x_{co}/x_m = 0.026$ and $E=0.58$, oscillogram 76-10 shows the broken Δ voltage V_Δ with a single line-to-ground fault on phase *a*. This, of course, is of fundamental frequency and approximately three times normal leg voltage. Oscillogram 77-5 shows the transient V_Δ to the same time and amplitude scale following the removal of the fault on phase *a* at a normal current zero without any subsequent restriking in the fault. It will be observed that this transient voltage is approximately half fundamental frequency. Oscillogram #77-6 shows, with the same calibration, the ultimate steady-state voltage appearing across the break in the Δ. It can be seen that this also is approximately one-half fundamental frequency, of very good wave form, and essentially of the same amplitude as though a line-to-ground fault were on the system.

This phenomenon is referred to as being essentially of $^1/_2$ frequency. Actually it differs from one-half fundamental frequency by a small amount such that line-to-neutral voltages vary with time at a very low beat frequency. Oscillogram 77-7 shows the transient recovery voltage on phase *a*. 77-11, 12, and 13 show the steady-state line-to-neutral voltages on phases *a*, *b*, and *c*, respectively. Oscillograms 77-14, 15, and 16 show the same three respective voltages at a later time to illustrate how slowly the voltages to ground are shifting, due to the "slip" frequency involved giving rise to a beat frequency component of voltage. Phase voltages reach a maximum of two times normal line-to-neutral crest for this case. Transformer currents may be very high for this condition because of the presence of this low frequency component of voltage as will be shown later.

The fundamental frequency phenomenon is illustrated by the oscillograms in figure 4*b* for $x_{co}/x_m = 0.123$ and $E=0.58$. Oscillograms 32-1, 2, and 3, show steady-state voltages to ground on phases *a*, *b*, and *c*, respectively, while 32-8 shows the sustained voltage appearing across the break in the Δ. This condition is very nearly the same as if a fault existed on phase *c* to ground. The voltage on phase *c* is very low—in fact, the fundamental frequency component appears to be practically zero. Voltages to ground on phases *a* and *b* are essentially line-to-line voltages of fundamental frequency, and the broken Δ voltage gives every indication of a fault without there being any fault on the system. The presence of subharmonics of one-half and of one-ninth frequency are evident in the oscillograms.

The third harmonic phenomenon is illustrated in figure 4*c* for $x_{co}/x_m=0.594$ and $E=1.0$. Oscillograms 32-9, 10, and 11 show voltages to ground (one cycle of fundamental frequency) on phases *a*, *b*, and *c*, respectively, while 32-16 shows the voltage appearing across the break in the Δ. The broken Δ voltage is of third harmonic frequency with good wave form and of higher magnitude than that obtained for a fault on the system. Voltages to ground on all three phases are the same in magnitude (about four times normal line-to-neutral crest). There are no subharmonics present in this case.

The normal condition for the same system ($x_{co}/x_m=0.594$) and operating voltage ($E=1.0$) is illustrated by the oscillograms in figure 4*d*. While the system constants are identical with those for the case discussed in the preceding paragraph

(d)

Figure 4d. Oscillograms illustrating the normal condition of some third harmonic voltage across the Δ break with balanced voltages-to-ground

$x_{co}/x_m=0.594$, $E=1.0$

Note: All voltage calibrations are times normal line-to-neutral crest voltage on the system side of the transformer the voltage conditions are quite different, corresponding to "normal" behavior of the circuit. As shown previously, circuits involving saturable impedance elements may give rise to voltage and current conditions which are not single valued functions of the circuit parameters.[5] For this case ($E=1.0$ and $x_{co}/x_m=0.594$), as in many others which could be used as illustrations, either of these conditions may be obtained, the one "abnormal" and the other "normal." Oscillograms 32-12 to -14, inclusive, show the balanced voltages-to-ground on phases a, b, and c, respectively, while 32-15 shows the broken Δ voltage. A third harmonic component is in evidence in this case also, but it is only a very small fraction of that present for the abnormal condition illustrated in oscillograms 32-9 to -11, inclusive, and 32-16. It is also much lower in magnitude than that obtained for the condition of a fault on the system.

Dividing lines between these three distinct modes of instability are not very clear-cut in all cases. For example, in the vicinity of $x_{co}/x_m=0.01$ but in the unstable region, $^1/_4$ frequency components of voltage were in evidence, although the $^1/_2$ frequency components predominated, other subharmonics were also present, sometimes of very low frequency, in this portion of the unstable region.

In the vicinity of $x_{co}/x_m=0.08$, the unstable phenomenon was mainly a combination of fundamental frequency and $^1/_2$ fundamental frequency. The dividing line might be considered as an indication of where for increasing values of x_{co}/x_m the phenomenon changes gradually from something predominantly of $^1/_2$ fre-

quency to something of predominantly fundamental frequency.

In the vicinity of $x_{co}/x_m=0.5$, the phenomena included a component of approximately twice normal frequency. This was observed only for a very limited range of values of x_{co}/x_m, and the other abnormal conditions occurring over greater ranges of this ratio, were considered of far greater importance.

These facts are pointed out merely to indicate the physical consistency of the information plotted in figure 3. The ratio x_{co}/x_m is proportional to the square of the natural frequency of the circuit studied. For very small values of this ratio, the circuit is always stable. As the ratio is increased beyond a certain value instability is encountered and the unstable phenomena are characterized in succession by voltage components of $^1/_4$, $^1/_2$, 1, 2, and 3 times normal frequency. Thus the predominant frequency of the phenomena is seen to increase consistently with the natural frequency of the circuit.

The effect of increased transformer resistance is shown in figure 5, i.e., greater than that shown in figure 3. It is of importance to note that the regions of instability are only very slightly affected by resistance over a practical range. This fact makes the results of the investigation much more widely applicable.

The results shown in figure 6 were obtained for the saturation curve #2 of figure 2. This curve is somewhat steeper than that likely to be encountered in most actual cases, but the results are of interest in that they show how the unstable regions are broadened and shifted so as to extend the range of instability to lower values of the ratio x_{co}/x_m. This effect is consistent with other phenomena observed in connection with circuit analysis involving saturable impedance elements.[5] The effect of saturation is to broaden the range of abnormality, the broadening effect increasing with increasing abruptness of saturation.

For line-to-line voltage rated potential transformers connected line-to-neutral $E=0.58$ and the regions of instability given in figure 3 are $0.013<x_{co}/x_m<0.075$ and $0.125<x_{co}/x_m<0.45$. Crest values of broken delta voltage, line-to-ground voltage, and of transformer current that may be obtained within these regions are given in figure 7. In the region corresponding to the fundamental frequency broken Δ voltage the voltage-to-ground of one phase is of small magnitude. The voltages-to-ground on the other two phases are approximately equal. Thus line voltages-to-ground as well as the broken Δ voltage are essentially the same as if a fault were on the system.

In the region corresponding to the one-half frequency broken Δ voltage condition, the voltages-to-ground are the same in magnitude on all three phases. However, an interval of several seconds must be considered for this to be true because of the slow "slip" frequency involved as previously described.
